(Dated: March 10, 2010)

The determination of the energy spectra of small spin systems as for instance given by magnetic molecules is a demanding numerical problem. In this work we review numerical approaches to diagonalize the Heisenberg Hamiltonian that employ symmetries; in particular we focus on the spin-rotational symmetry SU(2) in combination with point-group symmetries. With these methods one is able to block-diagonalize the Hamiltonian and thus to treat spin systems of unprecedented size. In addition it provides a spectroscopic labeling by irreducible representations that is helpful when interpreting transitions induced by Electron Paramagnetic Resonance (EPR), Nuclear Magnetic Resonance (NMR) or Inelastic Neutron Scattering (INS). It is our aim to provide the reader with detailed knowledge on how to set up such a diagonalization scheme.

I. INTRODUCTION

Magnetism is a research field that is almost as old as human writing. It took several thousand years until its nature, which is quantum, could be determined. In 1928 Werner Heisenberg published his work on the theory of ferromagnetism Zur Theorie des Ferromagnetismus, in which he introduced what is today called the Heisenberg model. That this spin-only model is successfully applicable to magnetism rests on the property of many iron group elements to possess a quenched angular momentum in chemical compounds. Therefore, for many magnetic substances the Heisenberg Hamiltonian provides the dominant term whereas effects connected to spin-orbit interaction are treated perturbatively in these systems. For theoretical work on non-Heisenberg systems see e.g. Refs. 3–7.

The Heisenberg Hamiltonian

\[ H_{\text{Heisenberg}} = -\sum_{i,j} J_{ij} \mathbf{s}(i) \cdot \mathbf{s}(j) \] (1)

models the magnetic system by a sum of pairwise interactions between spins. The interaction strength (exchange parameter) between spins at sites \( i \) and \( j \) is given by a number \( J_{ij} \) with \( J_{ij} < 0 \) referring to an antiferromagnetic and \( J_{ij} > 0 \) to a ferromagnetic coupling. The spins are described by vector operators.

In order to understand magnetic observables such as magnetization, susceptibility, heat capacity or EPR, NMR and INS spectra the knowledge of the full energy spectrum of the investigated small magnetic system as for instance a magnetic molecule is often indispensable. Although the Heisenberg Hamiltonian, Eq. (1), appears to be not too complicated, analytical solutions are known only for very small numbers of spins \( \leq 15 \) or for instance for the spin-1/2 chain via the Bethe ansatz. The attempt to diagonalize the Hamilton matrix numerically is very often severely restricted due to the huge dimension of the underlying Hilbert space. For a magnetic system of \( N \) spins of spin quantum number \( s \) the dimension is \((2s + 1)^N\) which grows exponentially with \( N \).

Group theoretical methods can help to ease this numerical problem. A further benefit is given by the characterization of the obtained energy levels by quantum numbers and the classification according to irreducible representations. This review intends to provide an overview of the latest developments in efficient numerical diagonalization techniques of the Heisenberg model using symmetries. In particular we focus on the spin-rotational symmetry \( SU(2) \) in combination with point-group symmetries.

The full rotational symmetry of angular momenta has been employed for quite a while. In quantum chemistry the method of irreducible tensor operators was adapted to few spin systems along with the upcoming field of molecular magnetism. Nowadays the computer program MAGPACK, that completely diagonalizes the Heisenberg Hamiltonian using \( SU(2) \) symmetry, is freely available. Also for the approximate determination of energy eigenvalues by means of Density Matrix Renormalization Group (DMRG) methods that can for instance treat chains of a few hundreds of spins with high accuracy, spin-rotational symmetry was employed.

In other fields such as nuclear physics this method was also adapted to model finite Fermi systems such as nuclei employing \( SU(2) \) symmetry. Early applications are also known for Hubbard models, where one can actually exploit two \( SU(2) \) symmetries.

Besides spin-rotational symmetry many magnetic molecules or spin lattices possess spatial symmetries that can be expressed as point-group symmetries. Nevertheless, a combination of \( SU(2) \) with point-group symmetries is not very common. The reason, as will become more apparent later, is that a rearrangement of spins due to point-group operations easily leads to complicated basis transformations between different coupling schemes. A possible compromise is to use only part of the spin-rotational symmetry (namely rotations about the \( z \)-axis) together with point-group symmetries or to expand all basis states in terms of simpler product states.
During the past years a few attempts have been undertaken to combine the full spin-rotational symmetry with point-group symmetries. Oliver Waldmann combines the full spin-rotational symmetry with those point-group symmetries that are compatible with the spin coupling scheme, i.e. avoid complicated basis transformations between different coupling schemes. Along the same lines, especially low-symmetry groups such as $D_2$ are often applicable since the coupling scheme can be organized accordingly, compare Ref. [55] for an early investigation. Sinitsyn, Bostrem, and Ovchinnikov follow a similar route for the square lattice antiferromagnet by employing $D_4$ point-group symmetry.

Very recently a general scheme was developed that allows to combine spin-rotational symmetry with general point-group symmetries. The key problem, that the application of point-group operations leads to states belonging to a basis characterized by a different coupling scheme whose representation in the original basis is not (easily) known, can be solved by means of graph theoretical methods that have been developed in another context. We discuss in detail how this method can be implemented and present results for numerical exact diagonalizations of Heisenberg spin systems of unprecedented size. Our aim is to provide the reader with sufficient material to be able to employ these powerful group theoretical methods. They can for instance also be applied to calculate higher order Wigner-$nJ$ symbols that appear when the double exchange is modeled via chemical bridges. Figure 1 shows such a simplification for a Cr$_8$ compound which can easily be modeled by a ring-like system of interacting spins.

The article is organized as follows. Section II introduces the basic concepts, i.e. the Hamiltonian and its properties, the irreducible tensor operators, point group operations, and the construction of basis states for irreducible representations. Section III demonstrates with the help of three examples that the Hamiltonian of spin systems of unprecedented size can be diagonalized completely. The outlook in Section IV shortly summarizes the main part of this article and shows perspectives. The main part of this article is contained in an extended appendix that explains all technical details to set up the discussed diagonalization scheme.

II. CONCEPTUAL IDEAS

A. Spin Hamiltonian of magnetic molecules

The research field of molecular magnetism deals with the investigation of the magnetic properties of chemical compounds composed of a number of ions that reaches from only a few up to dozens of it. For the magnetic modeling of the molecule only those ions are taken into account which possess unpaired electrons and thus a non-vanishing magnetic moment. Since the molecules, which are prepared in the form of a crystal or powder sample, are often quite well separated from each other by their ligands, inter-molecular interactions can be neglected in most cases. Additionally, the electrons can very often be treated as localized so that both features lead to a simplified sketch of the chemical compound, namely a spin system. The interactions between different spins of the system then depend of course on the chemical surrounding and stem from direct exchange or super-exchange via chemical bridges. Figure 1 shows such a simplification for a Cr$_8$ compound that can easily be modeled by a ring-like system of interacting spins.

A general Hamiltonian that models magnetic molecules could be written as

$$H_{\text{general}} = H_{\text{exchange}} + H_{\text{Zeeman}}, \quad (2)$$

where, to be more specific, in a system of $N$ spins, i.e. $i, j = 1, \ldots, N$, the two terms assume the form

$$H_{\text{exchange}} = \sum_{i,j} \mathbf{s}(i) \cdot \mathbf{J}_{ij} \cdot \mathbf{s}(j), \quad (3)$$

$$H_{\text{Zeeman}} = \mu_B \sum_i \mathbf{s}(i) \cdot \mathbf{g}_i \cdot \mathbf{B}. \quad (4)$$

$H_{\text{exchange}}$ describes in a compact way the (isotropic and anisotropic) exchange interaction between two single-spin vector operators $\mathbf{s}(i)$ and $\mathbf{s}(j)$ as well as the single-ion anisotropy. The quantity $\mathbf{J}_{ij}$ is a second rank Cartesian tensor containing the corresponding parameters. $H_{\text{Zeeman}}$ couples the spins to an external magnetic field $\mathbf{B}$. In general, the coupling to an external field can be anisotropic and is thus described by local tensors $\mathbf{g}_i$.

It turns out that for many magnetic molecules the isotropic Heisenberg Hamilton operator provides a very good model. In addition, we assume that for the highly symmetric spin systems to be treated in this article the $\mathbf{g}$-tensors are scalars, and the same for all ions. Then the resulting Hamiltonian that models the system simplifies to

$$H = H_{\text{Heisenberg}} + H_{\text{Zeeman}} \quad (5)$$
with

\[ H_{\text{Heisenberg}} = - \sum_{i,j} J_{ij} \vec{s}(i) \cdot \vec{s}(j) \quad (6) \]

\[ H_{\text{Zeeman}} = g \mu_B \vec{S} \cdot \vec{B} . \quad (7) \]

\( \vec{S} = \sum_{i} \vec{s}(i) \) is the total spin. As already mentioned, \( J_{ij} < 0 \) refers to an antiferromagnetic and \( J_{ij} > 0 \) to a ferromagnetic coupling.

The Heisenberg Hamiltonian is completely isotropic in spin space \((SU(2)\) \) symmetry), i.e. the commutators of the square of the total spin \( \vec{S} \) and its z-component \( S_z \) with \( H_{\text{Heisenberg}} \) vanish

\[ \left[ H_{\text{Heisenberg}}, S^2 \right] = 0 , \quad \left[ H_{\text{Heisenberg}}, S^z \right] = 0 . \quad (8) \]

Since \( \left[ S_x, S^z \right] = 0 \) the total magnetic quantum number \( M \) and the quantum number of the total spin \( S \) serve as good quantum numbers and a simultaneous eigenbasis of \( S^x, S^y \) and \( H_{\text{Heisenberg}} \) can be found.

A well adapted basis is then given by states of the form \( |\alpha S M\rangle \) which can be constructed according to a vector-coupling scheme (see App. A.2). These states are already eigenstates of \( S^x \) and \( S^y \) and \( \alpha \) denotes a set of additional quantum numbers resulting from the coupling of the single spins \( \vec{s}(i) \) to the total spin \( \vec{S} \). Due to Eqs. (8) the matrix elements of the Heisenberg Hamiltonian \( \langle \alpha'S' M'|H_{\text{Heisenberg}}|\alpha S M\rangle \) between states with different \( S \) and \( M \) vanish, leading to a block-factorized Hamilton matrix in which each block can be diagonalized separately. In this case the field dependence of the energies induced by the Zeeman term in Eq. (7) can easily be added without further complicated calculations. This is because the z-direction can be chosen to point along the external field, so that the Zeeman term commutes with \( H_{\text{Heisenberg}}, S^2 \) and \( S^z \). Then \( M \) still serves as a good quantum number, and the effect of the external field \( \vec{B} = B \cdot \vec{e}^z \) on eigenstates of \( H_{\text{Heisenberg}} \) results in a simple field dependence of the energy eigenvalues \( E_i \) according to

\[ E_i(B) = E_i + g \mu_B B M_i . \quad (9) \]

This way thermodynamic properties on the temperature \( T \) and the external magnetic field \( \vec{B} \) can easily be calculated from the energy spectrum of the investigated magnetic molecule once the energies \( E_i \) are known.

### B. Irreducible tensor operator method

The determination of the matrix elements of the Heisenberg Hamiltonian can elegantly be achieved with the help of irreducible tensor operators. To this end, it is necessary to reformulate the spin vector-operators in terms of irreducible tensor operators and to subsequently use tensorial algebra. In this regard the underlying theory is clearly based on group as well as representation theory. At this point it would probably not make sense to introduce all group-theoretical tools which lead to a complete understanding of the technical implementations used in this work. Several textbooks provide deep knowledge about these topics and the authors would like to refer to those. {15}{17} Nevertheless, at least the origin of appearing concepts and formulations shall be explained. Some understanding of abstract group and representation theory is assumed.

#### 1. Irreducible tensor operators

An irreducible tensor operator \( T^{(k)} \) of rank \( k \) is defined by the transformation properties of its components \( q \) under a general coordinate rotation \( R \) according to

\[ \tilde{D}(R)T^{(k)}_q \tilde{D}^{-1}(R) = \sum_{q'} T^{(k)}_{q'q} D^{(k)}_{qq'}(R) . \quad (10) \]

Here \( \tilde{D}(R) \) denotes the operator associated with the coordinate rotation \( R \). The subscripts \( q \) as well as \( q' \) take the values \( -k, -k+1, \ldots , k \). By \( \tilde{D}^{(k)}_{qq'}(R) \) the matrix elements of the so-called Wigner rotation matrices \( D^{(k)}(R) \) are denoted (cf. App. A.1).

The case \( k = 0 \) in Eq. (10) directly leads to what is called a scalar operator. As can easily be seen, a scalar operator is invariant under coordinate rotation, i.e. with \( D^{(0)}_{00}(R) = 1 \)

\[ \tilde{D}(R)T^{(0)}_q \tilde{D}^{-1}(R) = T^{(0)}_q D^{(0)}_{00}(R) = T^{(0)}_q . \quad (11) \]

In analogy to the states which span the irreducible representation \( D^{(1)} \) of \( R_3 \) and which are said to behave under coordinate rotations like the components of a vector the irreducible tensor operator \( T^{(1)} \) is called a vector operator. For example, the components of a first-rank irreducible tensor operator \( \tilde{x}^{(1)} \) derived from the Cartesian components of the spin vector operator are given by

\[ \tilde{x}^{(1)}_0 = \tilde{x}^z , \]

\[ \tilde{x}^{(1)}_{\pm 1} = \pm \sqrt{\frac{1}{2}} \left( \tilde{x}^x \pm i \tilde{x}^y \right) . \quad (12) \]

Stressing the analogy between the behavior of states and irreducible tensor operators under coordinate rotations, the role of the components \( T^{(k)}_q \) in Eq. (10) has to be specified. The components of the irreducible tensor operator \( T^{(k)} \) of rank \( k \) serve as a basis and therefore span the \((2k + 1)\)-dimensional irreducible representation \( D^{(k)} \) of the rotation group \( R_3 \).
For comparison, consider a group $\mathcal{G}$ and its irreducible representations $\Gamma(\mathcal{G})$. The direct product of the irreducible representations $\Gamma(i)$ and $\Gamma(j)$ separately spanned by two sets of basis vectors is given by $\Gamma(i) \otimes \Gamma(j)$. It is reducible (cf. Eq. (A2)) if linear combinations of the product functions can be found which transform as basis functions for an irreducible representation. This concept can – in a one-to-one correspondence – be extended to tensor operators since they behave like the above mentioned functions. As a result, the direct product of two irreducible tensor operators spanning $D^{(k_1)}$ and $D^{(k_2)}$ can be decomposed into irreducible representations spanned by linear combinations of the products $T^{(k_1)}_{q_1} T^{(k_2)}_{q_2}$. The coefficients of these linear combinations are the Clebsch-Gordan coefficients of Eq. (A4).

Formally, the direct product of two irreducible tensor operators is given by

$$\left\{ T^{(k_1)} \otimes T^{(k_2)} \right\}^{(k)}_q = \sum_{q_1 q_2} C_{q_1 q_2}^{k_1 k_2} T^{(k_1)}_{q_1} T^{(k_2)}_{q_2},$$

(13)

where possible values of the resulting rank $k$ can be determined in analogy to the vectorial coupling of spins and are given by $k = |k_1 - k_2|, |k_1 - k_2| + 1, \ldots, k_1 + k_2$. Equation (13) is a fundamental expression for the application of the irreducible tensor operator method within a numerical exact diagonalization routine. It leads to the desired formulation of the spin Hamiltonian in terms of irreducible tensor operators.

As an example, the coupling of the first rank irreducible tensor operators $U^{(1)}$ and $V^{(1)}$ according to Eq. (13) shall be presented here. Considering a compound irreducible tensor operator with $k = 0$, the coupling results in

$$\left\{ U^{(1)} \otimes V^{(1)} \right\}^{(0)} = \frac{1}{\sqrt{3}} \left( U_+^{(1)} V_-^{(1)} - U_0^{(1)} V_0^{(1)} + U_-^{(1)} V_+^{(1)} \right),$$

(14)

where for the Clebsch-Gordan coefficients the equation $C_{q_1 q_2}^{1,0,0} = 1/\sqrt{3} : (-1)^{q_1-q_2} \delta_{q_1 q_2}$ was used. Expressing the spherical components of $V^{(1)}$ and $U^{(1)}$ in terms of the Cartesian components in analogy to Eq. (12) yields

$$\left\{ U^{(1)} \otimes V^{(1)} \right\}^{(0)} = -\frac{1}{\sqrt{3}} \left( U^x V^x + U^y V^y + U^z V^z \right),$$

(15)

which is, apart from the prefactor, the scalar product of the Cartesian vector operators $U$ and $V$.

Finally, the problem of coupling irreducible tensor operators is identical to the coupling of angular momenta (cf. App. A4). Thus, from a mathematical point of view an advantage when using irreducible tensor operators is that one can adapt the mathematical approaches for coupling angular momenta and that one can refer to them.

2. Matrix elements of irreducible tensor operators

In the case of an irreducible tensor operator $T^{(k)}$ the matrix elements of this operator can be calculated according to the Wigner-Eckart theorem. It states for matrix elements with respect to spin states of the form $|\alpha S M\rangle$ that

$$\langle \alpha S M | T^{(k)} | \alpha' S' M' \rangle = (-1)^{S - M} \langle \alpha S | T^{(k)} | \alpha' S' \rangle \left( \begin{array}{cc} S & k \\ -M & q \end{array} \right),$$

(16)

The matrix element is apart from a phase factor decoupled into a Wigner-3J symbol and a quantity $\langle \alpha S | T^{(k)} | \alpha' S' \rangle$ called the reduced matrix element of the irreducible tensor operator $T^{(k)}$. The proof of Eq. (16) is given in standard textbooks about group theory and quantum mechanics. However, the physical meaning of this theorem and the consequences for the use within the irreducible tensor operator method shall be briefly discussed here.

First of all, it should be mentioned that the Wigner-Eckart theorem relies on the transformation properties of the appearing wave functions and operators. Furthermore, since the reduced matrix element is completely independent of any magnetic quantum number, the Wigner-Eckart theorem separates the physical part of the matrix element – the reduced matrix element – from the purely geometrical part reflected by the Wigner-3J symbol. The value of the reduced matrix element depends on the particular form of the tensor operator and the states (cf. App. A3) whereas the Wigner-3J symbol only depends on rotational symmetry properties. If a zero-rank ($k = 0$) irreducible tensor operator is assumed, the Wigner-3J symbol in Eq. (16) directly reflects that there is no transition between states $|\alpha S M\rangle$ with different $S$ or $M$. The matrix of the Heisenberg Hamiltonian from Eq. (20), which can be written as a zero-rank irreducible tensor operator (see App. A3), therefore takes block-diagonal form without further calculations.

According to Eq. (16) the calculation of the matrix element of an irreducible tensor operator is directly related to the calculation of the reduced matrix element of this operator. The reduced matrix element of an irreducible tensor operator $s^{(k)}$ with $k = 0, 1$, acting on a basis function of a single spin, can be derived from the evaluation of the Wigner-Eckart theorem. It yields the expressions

$$\langle s | s^{(0)} | s \rangle = \langle s \rangle \langle 1 | s \rangle = (2s + 1)^{1/2},$$

(17)

$$\langle s | s^{(1)} | s \rangle = \langle s \rangle (s + 1) (2s + 1)^{1/2},$$

(18)

where the zero-rank irreducible tensor operator of a single spin $s^{(0)}$ is given by the unity operator $1$ and the components of $s^{(1)}$ are given by Eq. (12).

Using Eq. (13) in combination with the Wigner-Eckart theorem in Eq. (16) and a decomposition of states
\[ \langle \alpha_1 s_1 \alpha_2 s_2 S || \mathbf{T}^{(k_1)} \otimes \mathbf{T}^{(k_2)} \rangle_q^{(k)} || \alpha'_1 s'_1 \alpha'_2 s'_2 S' \rangle = \] 
\[ [(2S + 1)(2S' + 1)(2k + 1)]^{\frac{1}{2}} \left( s_1 \ s'_1 \ k_1 \right) \] 
\[ \left( s_2 \ s'_2 \ k_2 \right) \] 
\[ \times \langle \alpha_1 s_1 || \mathbf{T}^{(k_1)} \rangle || \alpha'_1 s'_1 \rangle \langle \alpha_2 s_2 || \mathbf{T}^{(k_2)} \rangle \langle \alpha'_2 s'_2 \rangle . \] 

(19)

This is the reduced matrix element of a compound irreducible tensor operator of rank \( k \) which consists of the direct product of two irreducible tensor operators of general ranks \( k_1 \) and \( k_2 \).

Equation (19) is the basic formula for calculating reduced matrix elements of irreducible tensor operators composed of single-spin tensor operators as they appear in the Heisenberg Hamiltonian. By a successive application every irreducible tensor operator of that kind can be decoupled into a series of phase factors, Wigner-9J symbols and the reduced matrix elements of single-spin tensor operators (cf. Eq. (12)). The successive application of Eq. (19) is often called decoupling procedure since the compound tensor operator that describes the system under consideration is decoupled so that its reduced matrix element can be calculated (see App. A).

C. Point-group symmetries in Heisenberg spin systems

Magnetic molecules, for instance those of Archimedean type \([60-62]\) are often – not only from a scientific point of view – perceived to be of a special beauty (cf. Fig. 2). Certainly, this view is closely related to the high symmetry which can be found in the chemical structures and is referred to as point-group symmetry \([63]\). Point-group symmetries do not only contribute to the beauty of magnetic molecules, but they are also very instrumental in characterizing the energy levels of the spectra and thus in extracting physical information from the underlying spin system. Often a numerical exact diagonalization remains impossible unless point-group symmetries are used in order to reduce the dimensionality of the Hamilton matrices.

It must be emphasized that there is a clear difference between a group of symmetry operations in real space that map the molecule on itself and the corresponding group of symmetry operations in a many-body spin system. Since from a physical point of view a magnetic molecule is described by a system of interacting spins with a certain coupling graph (cf. r.h.s of Fig. 1), the term point-group refers rather to a group of symmetry operations on this coupling graph than to operations in real space. As a direct result, the group-theoretical characterization is also rather based on the symmetry of the coupling graph than on the molecular symmetry. Of course, since the number of appearing coupling constants as well as their strengths are estimated from the chemical structure of the molecule, there is a close connection between the symmetries of the molecule and the corresponding coupling graph but not necessarily a one-to-one correspondence.

In Heisenberg spin systems point-group symmetries can be included by mapping the symmetry operations on spin permutations. In order to emphasize this, the term spin-permutational symmetry instead of point-group symmetry is often used. However, in the work at hand the term point-group symmetry is used although the symmetry is always incorporated by mapping the point-group operations on spin permutations. In context to this, it has to be mentioned that in systems which include anisotropies the incorporation of point-group symmetries is much more complicated since rotations in real space have to be performed \([59,61,62]\).

FIG. 2: Sketch of the \{Mo_{72}Fe_{30}\} molecule (l.h.s., picture taken from Ref. \[67\]). The underlying spin system exhibits the structure of an icosidodecahedron, i.e. possesses icosahedral \((I_h)\) point-group symmetry (r.h.s.).

FIG. 3: Coupling graph of a square of identical spins \( s \) with \( D_4 \) symmetry axes (l.h.s) and a rectangle with \( D_2 \) symmetry axes (r.h.s.).
of a different strength $J'$ between spin pairs $<1, 4>$ and $<2, 3>$. In this case the coupling strength is indicated by the length of the coupling paths between the spins. The introduction of the second coupling constant then results in a reduction of the point-group symmetry from $D_4$ to $D_2$.

The point-group operations on the spin system can be identified with permutations of the spins that leave the Hamiltonian invariant. Such a permutation is represented by an operator $G(R_i)$ of the point-group $G$ for which the commutation relation

$$[\hat{H}_{\text{Heisenberg}}, G(R_i)] = 0 \quad (20)$$

holds, where $i = 1, \ldots, h$ numbers the symmetry operations up to the order $h$ of $G$.

The theory of group representations now provides the theoretical background for the use of point-group symmetries. The irreducible representations $\Gamma^{(n)}$ of a point-group $G$ can be used to classify the energy eigenstates of $\hat{H}_{\text{Heisenberg}}$ and to block-factorize the Hamilton matrices. The dimensionalities of the resulting subspaces, i.e. blocks, can be calculated with only little information. The irreducible matrix representations $\Gamma^{(n)}(R_i)$ of the group elements, i.e. the permutation operators, are somewhat arbitrary concerning the choice of the underlying basis. Thus, these elements are represented by their character, i.e. the trace of the particular matrix representation. The character $\chi^{(n)}(R_i)$ is invariant under unitary transformations and is in general given by

$$\chi^{(n)}(R) = \text{Tr} \Gamma^{(n)}(R) = \sum_{\lambda=1}^{l_n} \Gamma^{(n)}(R)_{\lambda\lambda}, \quad (21)$$

where $l_n$ denotes the dimension of the $n$-th irreducible representation $\Gamma^{(n)}$.

A given character table of $G$ now enables one to calculate the dimensions of the resulting blocks within the Hamilton matrix, i.e. the dimensions of the subspaces $H(S, M, \Gamma^{(n)})$. Character tables for various point-groups can be found in almost every textbook about the theory of group representations. The authors would like to refer to these concerning the construction of character tables.

In order to calculate the dimensions of the subspaces $H(S, M, \Gamma^{(n)})$, the reducible matrix representations $G(R_i)$ of the operators $G(R_i)$ have to be considered. With $l, m = 1, \ldots, \dim H(S, M)$ the matrix elements of these matrices are given by

$$G(R_i)_{lm} = \langle \alpha_l S M | G(R_i) | \alpha_m S M \rangle,$$

where the subscripts attached to $\alpha$ indicate that specific basis states are considered. The decomposition of the character $\chi(R_i) = \sum_{n} G(R_i)_{n} n$ with respect to the irreducible representations $n$ of $G$ then yields

$$\chi(R_i) = \sum_{n} a_n \chi^{(n)}(R_i). \quad (22)$$

Using the great orthogonality theorem the above equation results in the expression

$$a_n = \dim H(S, M, \Gamma^{(n)}) = \frac{1}{h} \sum_{k} N_k [\chi^{(n)}(C_k)]^* \chi(C_k), \quad (23)$$

where $a_n$ gives the multiplicity of the irreducible representation $\Gamma^{(n)}$ that is contained in the reducible representation $G(C_k)$. $C$ refers to the classes which the group elements can be divided in. Each class contains equivalent operations, for example $n$-fold rotations, which are linked by the same group operation and thus hold the same character. $N_k$ denotes the number of elements of $C_k$.

From Eq. (23) the dimensions of the subspaces $H(S, M, \Gamma^{(n)})$ can be calculated, but no information about the basis states that span these Hilbert spaces is given. The required symmetrized basis states can be determined by the application of the projection operator

$$P^{(n)}_{\kappa\kappa} = \frac{l_n}{h} \sum_{i} \left[ \Gamma^{(n)}(R_i)_{\kappa\kappa} \right]^* G(R_i). \quad (24)$$

This operator projects out that part of a function $|\phi \rangle$ which belongs to the $\kappa$-th row of the irreducible representation $\Gamma^{(n)}$. A subsequent application of the operator in Eq. (24) on basis states, for example of the form $|\alpha S M \rangle$, is called the basis-function generating machine.

Although Eq. (24) provides the information required to construct symmetrized basis states that serve as a basis for the irreducible representations of $G$, it is important to notice that the matrices of $\Gamma^{(n)}$ have to be known completely. Of course, this does not cause a problem as long as $G$ entirely consists of one-dimensional irreducible representations. However, if more-dimensional irreducible representations appear, it is often more convenient to use the projection operator

$$P^{(n)} = \sum_{\kappa} P^{(n)}_{\kappa\kappa} = \frac{l_n}{h} \sum_{i} [\chi^{(n)}(R_i)]^* G(R_i), \quad (25)$$

that only requires information which can be extracted from the character table of $G$. The operator of Eq. (25) projects out that part of a function $|\alpha S M \rangle$ which belongs to the irreducible representation $\Gamma^{(n)}$, irrespective of the row. As a consequence one has to orthonormalize resulting functions – for example by a Gram-Schmidt orthonormalization – in order to obtain the correct symmetrized basis functions (cf. App. [A.3]).

D. Point-group symmetry operations acting on vector-coupling states

In the previous section some general remarks about the use of point-group symmetries have already been made. In order to transform the Hamilton matrix
to a block-diagonal form with respect to irreducible representations $\Gamma^{(n)}$ of a point group $G$, one has to construct symmetrized basis functions $|\alpha S M \Gamma^{(n)}\rangle$. Equation (25) provides the projection operator that projects out that part of a state which belongs to the $n$-th irreducible representation of $G$. However, the main challenge when constructing symmetrized basis states is to find an expression for the action of the operators $G(\pi)$ on states of the form $|\alpha S M \rangle$.

The above mentioned operators $G(\pi)$ which correspond to operations on the coupling graph (cf. Fig. 3) can be defined by their action on the product basis composed of the single-spin eigenstates of $\hat{S}_z(i)$. The states of the product basis of $N$ identical spins can be denoted by

$$|s_1m_1\rangle \otimes |s_2m_2\rangle \otimes \cdots \otimes |s_Nm_N\rangle \equiv |m_1 m_2 \ldots m_N\rangle$$

and fulfill the eigenvalue equation

$$\hat{S}_z(i) |m_1 \ldots m_i \ldots m_N\rangle = m_i |m_1 \ldots m_i \ldots m_N\rangle$$

according to their definition.

Now, in a spin system consisting of $N$ spins an operator $G(\pi)$ is considered that is given in the form $G(\pi(1) \pi(2) \ldots \pi(N))$ and describes a point-group operation. The notation $G(\pi)$ indicates for all $i = 1, \ldots, N$ that the point-group operation interchanges the spin at site $i$ with the spin at site $\pi(i)$. The action of the operator $G(\pi)$ on the product basis is given by

$$G(\pi)|m_1 m_2 \ldots m_N\rangle = |m_{\pi(1)} m_{\pi(2)} \ldots m_{\pi(N)}\rangle.$$ (26)

In Eq. (26) the following happens: by the action of $G(\pi)$ the single-spin system at site $i$ takes the $z$-component which the system at site $\pi(i)$ has taken previously. The result is a different state of the product basis with permuted $m$-values.

The operators $G(\pi)$ are only defined by their action on product states whereas the details of constructing symmetrized basis states that are linear combinations of vector-coupling states of the form $|\alpha S M \rangle$ are still unknown. How to find an expression for the action of $G(\pi)$ on these vector-coupling states is – to some extent – shown in Refs. 34 and 37.

However, a slightly different perspective concerned with the application of general symmetry operations to a vector-coupling basis shall be presented here (for further technical details see App. A 3). In order to clarify the action of an operator representing a point-group operation on a vector-coupling state, the states are labeled according to the coupling scheme they are belonging to. Additionally, the set of quantum numbers referring to the coupling scheme is abbreviated by Greek letters. Primed indicate different basis states within the same coupling scheme. With these conventions one obtains the following general result for a transition between two coupling schemes $a$ and $b$ which is induced by an operator $G$ representing a point-group operation:

$$G|\alpha S M \rangle_a = \delta_{\alpha,\beta} |\beta S M \rangle_b.$$ (27)

The Kronecker symbol $\delta_{\alpha,\beta}$ on the right hand side indicates that the values of the spin quantum numbers of the different sets $\alpha$ and $\beta$ are the same. Re-expressing the right hand side of Eq. (27) within states belonging to the coupling scheme $a$, i.e. inserting a suitable form of the identity operator $\sum$, directly leads to the very important final result

$$G|\alpha S M \rangle_a = \sum_{\alpha'} \delta_{\alpha,\alpha'} |\alpha' S M \rangle_b |\alpha' S M \rangle_a$$ (28)

which contains so-called general recoupling coefficients $a(\alpha S M |\beta S M \rangle_b$ $a S M \rangle_a$. A general recoupling coefficient can be seen as a scalar product between vector-coupling states belonging to different coupling schemes $a$ and $b$.

It is by no means trivial to find an expression for a recoupling coefficient relating different coupling schemes if more than three or four spins are present. By definition the expressions for the elements of the transition matrix relating two different coupling schemes result in Wigner-nJ symbols (cf. App. A 1). While for three interacting spins Wigner-6J symbols occur, the size of these Wigner coefficients increases with every additional spin taken into account. For four interacting spins the recoupling coefficient is expressed by a Wigner-9J symbol and for five interacting spins the recoupling is described by Wigner-12J symbols.

From a computational point of view it turns out to be unfavorable to use algebraic expressions for higher symbols than Wigner-9J symbols although there exist expressions for 12J symbols and 15J symbols. In order to find an effective way to describe general recoupling coefficients, one should use expressions in which only Wigner-6J symbols appear. These 6J symbols can be calculated using the formula

$$\begin{vmatrix} j_1 & j_2 & j_3 \\ J_1 & J_2 & J_3 \end{vmatrix} = \Delta(j_1, j_2, j_3) \Delta(j_1, J_2, J_3) \times \Delta(J_1, j_2, J_3) \Delta(J_1, J_2, j_3) \sum_{t} \frac{(-1)^{t}(l+1)!}{f(t)},$$ (29)

where the triangle coefficient $\Delta(a, b, c)$ reads

$$\Delta(a, b, c) = \left( \frac{(a + b - c)!(a - b + c)!(a + b + c)!}{(a + b + c + 1)!} \right)^{\frac{1}{2}}.$$ 

The function $f(t)$ in Eq. (29) is given by

$$f(t) = (t - j_1 - j_2 - j_3)! (t - j_1 - J_2 - J_3)! \times (t - J_1 - j_2 - J_3)! (t - J_1 - J_2 - j_3)! \times (j_1 + j_2 + J_1 + J_2 - t)! (j_2 + j_3 + J_2 + J_3 - t)! \times (j_3 + j_1 + J_3 + J_1 - t)!.$$
The sum in Eq. (29) is running over nonnegative integer
values of $t$ for which no factorial in $f(t)$ has a negative
argument. Since even the evaluation of Wigner-6J symbols
is a rather involved task as can be seen from Eq. (29),
it is helpful to analyze the symmetry properties of the
appearing symbols (cf. Fig. 14) in order to reduce the
computational effort when constructing symmetrized ba-
sis states. In this regard, when expressing the action of
a point-group operation on a basis state according to
Eq. (28), only those recoupling coefficients have to be
calculated which are non-zero.

So far, nothing has been said about the generation of
a formula that describes a general recoupling coefficient.
Finding a formula which only contains Wigner-6J sym-
}
FIG. 5: Full energy spectrum of a cuboctahedron with \( s = 3/2 \). The energy levels have been calculated using \( D_2 \) point-group symmetry.

in Fig. 5 could be numerically evaluated using the \( D_2 \) point-group symmetry. For low-lying sectors of \( S = 0, 1, 2, 3 \) we also determined the energy levels according to irreducible representations of the full octahedral group \( O_h \), see Fig. 6. One feature that can be clearly seen in Fig. 6 is the existence of an additional low-lying singlet below the first triplet.

FIG. 6: Low-lying part of the energy spectrum of a cuboctahedron \( s = 3/2 \). The energy levels are labeled according to irreducible representations of the full octahedral group \( O_h \).

FIG. 7: Magnetization as a function of applied field at \( T = 0 \) for the regular cuboctahedron with \( s = 3/2 \). This curve shows the aforementioned plateau at 1/3 of the saturation magnetization and a jump to saturation of height \( \Delta M = 2 \).

FIG. 8: Zero-field heat capacity (top) and zero-field susceptibility (bottom) for the regular cuboctahedron with \( s = 1/2, s = 1, \) and \( s = 3/2 \).

Figure 8 compares the heat capacity (top) and the zero-field susceptibility (bottom) for the regular cuboctahedron with \( s = 1/2, s = 1, \) and \( s = 3/2 \). The heat capacity shows a pronounced double peak structure for \( s = 1/2 \) and \( s = 1 \) which dissolves into a broad peak with increasing spin quantum number. The broad peak also moves to higher temperatures with increasing \( s \). The reason for the first sharp peak is twofold. Since there are several gaps between the low-lying levels the density of states has a very discontinuous structure which results in the double peak structure. For \( s = 1/2 \) the low-lying singlets provide a very low-lying non-magnetic density of states which is responsible for the fact that the first sharp peak is at such low temperatures. For \( s = 1 \) the first sharp peak results from both excited singlet as well as lowest triplet levels. For \( s = 3/2 \) a remnant of the first sharp peak is still visible; it is given by the low-lying singlets, but since they are so few, also influenced by the lowest triplet levels. The behavior of the heat capacity is contrasted by the susceptibility, bottom of Fig. 8, which reflects mostly the density of states of magnetic levels and is only weakly influenced by low-lying singlets. Therefore, the first sharp peak, or any other structure at very low temperatures, is absent.
B. The icosahedron

A spin system where the spins are mounted at the vertices of an icosahedron and interact antiferromagnetically along the edges seems to be rather appealing since it exhibits unusual frustration properties such as metamagnetic phase transitions. Unfortunately, it appears to be challenging to synthesize such structures although icosahedra are rather stable cluster configurations.

Here we investigate the properties of an icosahedron \((N = 12)\) with single spin quantum number \(s = 3/2\) (Hilbert space dimension 16,777,216). The complete set of energy eigenvalues has been determined using \(D_2\) symmetry. Figure 9 displays the low-lying part of all levels. Looking at the data file it turns out that very many (really unusually many) levels are highly degenerate, which is in accordance with earlier investigations of icosahedra with smaller single spin quantum number. We find that for every sector of total spin \(S\) and total magnetic quantum number \(M\) the irreducible representations \(A_2, B_1,\) and \(B_2\) contain exactly the same energy eigenvalues, whereas \(A_1\) is different. The non-degenerate ground state belongs to \(A_1\). In addition very often near degeneracies occur.

Figure 10 shows the related zero-field heat capacity (top) and zero-field susceptibility (bottom). While the susceptibility does not look so unusual compared to other spin structures, the heat capacity appears to be really weird. Half way up the initial rise at very low temperatures there is a Schottky-like peak that stems from the slightly split ground state \((S = 0)\) levels. The further rise is due to the fact that the lowest \(2 \times 3\) degenerate \((S = 1)\) level is energetically rather close. Although higher-lying levels are separated by gaps from the lowest levels they also contribute to the heat capacity due to their massive degeneracy. Altogether this results in a low-temperature heat capacity that is much larger than the heat capacity of the cuboctahedron, compare Fig. 8.

The icosahedron may also serve as an example for the technical complexity due to the evaluation of recoupling coefficients. When combining \(I_h\) symmetry with \(SU(2)\) many different recoupling formulas have to be generated (119 for the 120 group operations minus identity to be precise). This renders a treatment of the \(s = 3/2\) icosahedron in \(I_h\) impossible. Although the sizes of the Hamilton matrices for the irreducible representations would be small, it is the construction of basis states that turns the evaluation of the needed matrix elements into a very lengthy procedure. Even in a parallelized job on 256 cores on a supercomputer this task could not be completed. For the \(s = 1\) icosahedron we could finish a decomposition into irreducible representations of the full icosahedral group \(I_h\).
resentations of the full icosahedral group $I_h$. The exact and near degeneracies that have been discussed above for the case of $s = 3/2$ and $D_2$ can now be resolved. For instance, the lowest $S = 1$ level belongs to $T_{2u}$ and is thus threefold degenerate. It is split from the higher-lying $T_{2g}$ by only $3/1000 |J|$ which in any calculation or measurement would look like a six-fold degeneracy, see also Ref. 93.

C. Rings

Molecular ferric wheels are among the very first magnetic molecules. It appears that they can be synthesized in many even numbered sizes, e.g. $N = 6, 8, \ldots, 18$ Fe(III) spins.\textsuperscript{70,98–102} Since the spin of the Fe(III) ions is $s = 5/2$ the Hilbert space dimension grows rapidly from one ring size to the next. For the ferric wheel Fe$_{10}$ it reaches already 60,466,176 rendering a complete diagonalization impossible, at least in the past.\textsuperscript{70} Based on the observation that the lowest energy eigenvalues $E_{\text{min}}(S)$ obey a quadratic dependence with respect to total spin,\textsuperscript{38,43,103–106} which is Lande’s interval rule, approximations could be derived for the level crossing field\textsuperscript{103} as well as for low-lying excitations in for instance the truly giant ferric wheel Fe$_{18}$.\textsuperscript{107} As mentioned earlier, QMC is also capable of evaluating observables for even-membered unfrustrated spin rings\textsuperscript{76} Nevertheless, none of the methods is able to determine higher-lying states.

In the following we present the first complete diagonalization study of a spin ring similar to Fe$_{10}$, i.e. with $N = 10$ and $s = 5/2$. This enables us to subsequently evaluate all thermodynamic functions, all excited levels, and if needed even the evolution for time-dependent observables. For the diagonalization we used only the $D_2$ symmetry because it reduces the matrices already sufficiently and allows a faster computation of recoupling coefficients and thus matrix elements compared to the $C_{10}$ symmetry.

Figure 12 displays the low-lying energy levels for various sectors of total spin $S$. The rotational band structure of energy levels, which is at the heart of the aforementioned approximation, is clearly visible. Having obtained the eigenvalues an evaluation of the magnetization as function of temperature and field is easily possible. Figure 13 shows the susceptibility as function of temperature (top) and the magnetization as function of applied field (bottom) of an antiferromagnetically coupled spin ring with $N = 10$ and $s = 5/2$. The exchange parameter $J = -9.6 \text{ cm}^{-1}$ as well as the susceptibility data are taken from Ref. 70.

IV. OUTLOOK

In this review we have undertaken the attempt to explain how numerical approaches to diagonalize the Heisenberg Hamiltonian work, that employ the spin-rotational symmetry SU(2) in combination with point-group symmetries. We hope that we could provide the reader with detailed knowledge on how to set up such a diagonalization scheme, especially through the extended technical appendix.

What remains open for the future is to develop efficient schemes to evaluate recoupling coefficients, which at the present stage can be a very time consuming procedure that sometimes renders the calculation of matrix elements rather small in the end. A natural next step is to develop an appropriate basis and set up optimal coupling schemes for a given molecule and point-group symmetry. We hope that we could provide the reader with detailed knowledge on how to set up such a diagonalization scheme, especially through the extended technical appendix.

Appendix A: Realization of the irreducible tensor operator technique

In this section the theoretical foundations presented in Sec. IV shall be specified. To this end, after having developed a basic idea of the coupling of angular momenta a spin square deals as a small example system. It is demonstrated how an appropriate basis can be constructed and how the Heisenberg Hamiltonian looks like when expressed in terms of irreducible tensor operators. Further on, it is shown how the matrix elements can be evaluated by decoupling the irreducible tensor operator that describes the system. A central aspect is the use of point-group symmetries in combination with irreducible tensor operators that leads to the occurrence of general recoupling coefficients.

1. Coupling of angular momenta and Wigner-nJ symbols

As a first step the coupling of two general angular momenta \( j_1 \) and \( j_2 \) shall be discussed. Regarding this, the work at hand mainly refers to the use of definitions and name conventions that have been introduced by Wigner.\(^{20}\)

The vector coupling rule for the addition of angular momenta, known from elementary atomic physics, states that the resulting angular momenta \( J \) can be characterized by a quantum number \( J \). \( J \) assumes all values

\[
|j_1 - j_2|, |j_1 - j_2| + 1, \ldots, j_1 + j_2 - 1, j_1 + j_2,
\]

where \( j_1 \) and \( j_2 \) denote the quantum numbers of the angular momenta \( j_1 \) and \( j_2 \). Equation (A1) is also referred to as triangular condition for the coupling of two angular momenta.

From a group-theoretical point of view the eigenstates \( |j m\rangle \) of \( \vec{j}^2 \) and \( \vec{j}^2 \) span a \((2j + 1)\)-dimensional irreducible representation \( D(j) \) of the group \( R_3 \), i.e. the group of all rotations within three-dimensional space. Keeping this in mind, the above vector addition rule Eq. (A1) is equivalent to

\[
D(j_1) \otimes D(j_2) = \sum_{J=|j_1-j_2|}^{j_1+j_2} D(J).
\]

According to this equation, the direct product between two irreducible representations of the dimensions \((2j_1 + 1)\) and \((2j_2 + 1)\), which in general reducible, decays into \((2J + 1)\)-dimensional irreducible representations with respect to \( J \).

Now, the operators \( D(j_1)(R) \) and \( D(j_2)(R) \) are associated with an arbitrary coordinate rotation \( R \) of \( R_3 \) and operate in the Hilbert spaces spanned by \(|j_1 m_1\rangle\) and \(|j_2 m_2\rangle\). What does Eq. (A2) mean for the direct product \( D(j_1)(R) \otimes D(j_2)(R) \) of the corresponding matrix representations? The product can be transformed into a block-diagonal form \( U(R) \) by a unitary matrix \( A \), i.e.

\[
D(j_1)(R) \otimes D(j_2)(R) = A^\dagger U(R) A,
\]

where \( U(R) \) has the form

\[
U(R) = \begin{bmatrix}
D(|j_1-j_2|)(R) & 0 & \cdots & 0 \\
0 & D(|j_1-j_2|+1)(R) & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & D(j_1+j_2)(R)
\end{bmatrix}.
\]

The matrices \( D(j)(R) \) appearing therein comprise matrix elements with respect to those functions that span the irreducible representations \( D(j) \) in Eq. (A2).

The determination of the elements of the transformation matrix \( A \) has been a central task in the theory of group representations. The elements of \( A \) are the so-called Clebsch-Gordan coefficients \( C_{m_1 m_2 M}^{j_1 j_2 J} \). They appear in a more familiar form as scalar products between...
a state of the form \( |j_1 j_2 J M \rangle \) and the product states \( |j_1 m_1 j_2 m_2 \rangle \) leading to the decomposition

\[
|j_1 j_2 J M \rangle = \sum_{m_1, m_2} \langle j_1 m_1 j_2 m_2 | j_1 j_2 J M \rangle |j_1 m_1 j_2 m_2 \rangle
= \sum_{m_1, m_2} C_{m_1, m_2}^{j_1 j_2 J} |j_1 m_1 j_2 m_2 \rangle .
\] (A4)

The Clebsch-Gordan coefficients therefore relate two different orthonormal sets of basis vectors. It should be emphasized that these sets are obviously not orthogonal to each other because they span the same space. The Clebsch-Gordan coefficients are non-zero only if the vector addition rule from Eq. (A1) and simultaneously the equation \( m_1 + m_2 = M \) hold. A very important symmetry of the Clebsch-Gordan coefficients is

\[
C_{m_1, m_2}^{j_1 j_2 J} = (-1)^{j_1 + j_2 - J} C_{m_1, m_2}^{-j_1 - j_2 + J} ,
\] (A5)

with \((-1)^{j_1 + j_2 - J} = \pm 1\) according to Eq. (A1).

In order to reveal the symmetry properties of the Clebsch-Gordan coefficients, they are reformulated in a straightforward manner. A proper reformulation leads to the Wigner coefficients or Wigner-3J symbols

\[
\begin{pmatrix} j_1 & j_2 & J \\ m_1 & m_2 & M \end{pmatrix}
\]

which are related to the Clebsch-Gordan coefficients by

\[
\begin{pmatrix} j_1 & j_2 & J \\ m_1 & m_2 & M \end{pmatrix} = \frac{1}{\sqrt{2}} \left( (-1)^{j_1 - j_2 - M} (2J + 1)^{-\frac{1}{2}} C_{m_1, m_2}^{j_1 j_2 J} \right).
\] (A6)

The relation between Clebsch-Gordan coefficients and the Wigner-3J symbols from Eq. (A6) directly leads to non-zero values of the Wigner-3J symbols only if \( m_1 + m_2 + M = 0 \) holds and the vector addition rule from Eq. (A1) is fulfilled.

Expressed in terms of Wigner-3J symbols the symmetry property of the Clebsch-Gordan coefficients given in Eq. (A5) takes the form

\[
\begin{pmatrix} j_1 & j_2 & J \\ m_1 & m_2 & M \end{pmatrix} = (-1)^{j_1 + j_2 + J} \begin{pmatrix} j_2 & j_1 & J \\ m_2 & m_1 & M \end{pmatrix} .
\] (A7)

Thus, the Wigner-3J symbols are invariant under an even number of permutations of the columns whereas under a single permutation they obey Eq. (A7). A further evaluation of the symmetry properties of the Clebsch-Gordan coefficients yields an additional symmetry of the Wigner-3J symbols, i.e.

\[
\begin{pmatrix} j_1 & j_2 & J \\ m_1 & m_2 & M \end{pmatrix} = (-1)^{j_1 + j_2 + J} \begin{pmatrix} j_1 & j_2 & J \\ -m_1 & -m_2 & -M \end{pmatrix} .
\] (A8)

So far the coupling of only two angular momenta has been considered. A procedure similar to the one which has led to the Wigner-3J symbols now leads to the occurrence of Wigner-6J symbols. In the case of a coupling of three angular momenta, \( \mathbf{J} = \mathbf{j}_1 + \mathbf{j}_2 + \mathbf{j}_3 \), a basis can be constructed in which the representations of the operators \( \mathbf{J}^2 \) and \( J^z \) as well as \( j_1^z, j_2^z, \) and \( j_3^z \) are diagonal. Obviously, there exists a certain freedom of choice in the construction of this basis. The resulting \( \mathbf{J} \) can be constructed in three different ways, namely

\[
\mathbf{J} = (\mathbf{j}_1 + \mathbf{j}_2) + \mathbf{j}_3 ,
\] (A9)

\[
\mathbf{J} = \mathbf{j}_1 + (\mathbf{j}_2 + \mathbf{j}_3) ,
\] (A10)

\[
\mathbf{J} = (\mathbf{j}_1 + \mathbf{j}_3) + \mathbf{j}_2 .
\] (A11)

This leads to three different basis sets, each with the square of one of the operators \( \mathbf{J}^2 = j_1^2 + j_2^2 + j_3^2 \), and \( j_1^z = j_2^z = j_3^z \) given in a diagonal form. The matrix elements of the unitary transformation matrix which connects two of these sets of basis states can be found as scalar products between states belonging to two different coupling schemes. Expressing a state belonging to a coupling scheme resulting from a coupling according to Eq. (A9) in terms of states belonging to the scheme resulting from Eq. (A10) yields

\[
|j_1 j_2 j_3 J M \rangle = \sum_{j_{23}} \langle j_1 j_2 j_3 j_{23} | j_1 j_2 j_3 J M \rangle |j_1 j_2 j_3 j_{23} \rangle ,
\] (A12)

with the quantum numbers \( j_{23} \) and \( j_{23} \) referring to \( j_{12}^2 \) and \( j_{12}^2 \), respectively.

Scalar products of the kind found in Eq. (A12) – often called recoupling coefficients – are independent of any magnetic quantum number. They can be evaluated by decomposing the vector-coupling states into a sum of product states with the help of an extended version of Eq. (A4). For example, the decomposition of the ket on the left hand side of the aforementioned recoupling coefficients yields

\[
\langle j_1 j_2 j_3 J M | j_1 j_2 j_3 j_{23} j M \rangle = \sum_{m_1, m_2, m_3} \langle j_1 m_1 j_2 m_2 j_3 m_3 j_{12} j_{23} j M \rangle \times \langle j_1 m_1 j_2 m_2 j_3 m_3 \rangle .
\] (A13)

The scalar products in Eq. (A13), i.e. the matrix elements of the transformation matrix that connects the vector-coupling state with the product states, are called in analogy to the former name convention generalized Clebsch-Gordan coefficients \( C_{m_1 m_2 m_3 m_{23}}^{j_1, j_2, j_3 J} \) for the coupling of three angular momenta. They can be simplified to a product of Clebsch-Gordan coefficients according to

\[
C_{m_1 m_2 m_3 m_{23}}^{j_1, j_2, j_3 J} = \sum_{m_{23}} C_{m_2 m_3 m_{23}}^{j_2 j_3 J} C_{m_1, m_{23}}^{j_1 J} .
\] (A14)
As one can see, generating generalized Clebsch-Gordan coefficients for the coupling of more than three angular momenta and – in addition – an expression of it in terms of Clebsch-Gordan coefficients is then a straightforward task. Here it should be mentioned that according to Eq. (A14) generalized Clebsch-Gordan coefficients can also be expressed as a sum over products of Wigner-3J symbols using the relation from Eq. (A6). Coefficients of this kind are then called generalized Wigner coefficients.

The recoupling coefficients that appear in Eq. (A12) can now be reformulated in terms of Wigner-6J symbols in order to reveal their symmetry properties. For the transition between the basis sets belonging to \( j_{12} \) and \( j_{23} \) the corresponding Wigner-6J symbol is related to the recoupling coefficient by

\[
\{ j_1 \, j_2 \, j_{12} \, j_3 \, j_4 \, j_{23} \} = (-1)^{j_1+j_2+j_3+j_4-j_{12}-j_{23}} (2j_{12}+1)^{-\frac{1}{2}} \times (2j_{23}+1)^{-\frac{1}{2}} \langle j_1 \, j_2 \, j_{12} \, j_3 \, j_4 \, j_{23} \rangle \langle j_{12} \, j_{23} \rangle .
\]  

(A15)

Equations (A13) and (A14) directly show that a Wigner-6J symbol can be expressed as a sum over products of Wigner-6J symbols and over products of Wigner-3J symbols.

For the sake of completeness, also the Wigner-9J symbols shall be given which result as elements of the transition matrices when recoupling four angular momenta. For example the transition between two different sets of basis states yields a Wigner-9J symbol like

\[
\frac{1}{2} \langle j_1 \, j_2 \, j_{12} \, j_3 \, j_4 \, j_{13} \, j_5 \, j_{24} \rangle = \frac{1}{2} [\langle j_1 \, j_2 \, j_{12} \, j_3 \, j_4 \, j_{13} \, j_5 \, j_{24} \rangle ]^{-\frac{1}{2}} \times [\langle j_1 \, j_2 \, j_{12} \, j_3 \, j_4 \, j_{13} \, j_5 \, j_{24} \rangle ]^{-\frac{1}{2}} \times [\langle j_1 \, j_2 \, j_{12} \, j_3 \, j_4 \, j_{13} \, j_5 \, j_{24} \rangle ]^{-\frac{1}{2}}
\]  

(A16)

A very comprehensive overview of algebraic expressions for Wigner-NJ symbols as well of their symmetry properties is given in Ref. [55]. Regarding the use of Wigner symbols in connection with irreducible tensor operators, here only a graphical visualization of the triangular conditions for a Wigner-6J symbol is shown. The Wigner-6J symbol is nonzero only if for certain triads of quantum numbers the triangular condition (Eq. (A11) holds. For which combination of quantum numbers of angular momenta the triangular condition has to be valid in order to yield a nonzero Wigner-6J symbol, is visualized graphically in Fig. 14

![Graphical visualization of the four triangular conditions occurring in a Wigner-6J symbol which have to be valid in order to yield a nonzero result.](Image)

2. The construction of basis states

The reduction of the dimensionalities of the Hilbert spaces in which the Hamilton matrices are set up in order to solve the eigenvalue problem is always a desirable, but also numerically involved task. Especially if the basis a priori reflects symmetry properties of the system, an appropriate choice can be of great help. As mentioned in Sec. II a basis that consists of vector-coupling states and incorporates full spin-rotational (SU(2)) symmetry would be the first choice. In isotropic spin systems as described by a Heisenberg Hamiltonian the Hamilton matrix is then block-diagonalized with respect to \( S \) and \( M \) without further calculations since there are no transition elements between states of a different total magnetic quantum number \( M \) and different total-spin quantum number \( S \).

The vector-coupling states used in the present work appear in the form \( | \alpha S M \rangle \), \( \alpha \) denotes a set of intermediate quantum numbers resulting from the chosen coupling scheme according to which the spins are coupled. As mentioned in the previous section the choice of the coupling scheme is somewhat arbitrary since it only reflects the bracketing in the expression for the total spin operator of the system \( \mathbf{S} = \sum_i \mathbf{s}_i \).

The simplest choice of a coupling scheme would probably be a successive coupling of the single-spin vector operators \( \mathbf{s}_i \). In the case of a spin square the set of intermediate quantum numbers, if coupled according to a successive coupling scheme, looks like

\[ \alpha = \{ s_{12} = \mathbf{s}_1, s_{123} = \mathbf{s}_2 \} \]

leading to a vector-coupling state of the form \( | s_{12} \mathbf{s}_1 \mathbf{s}_2 \mathbf{s}_4 S M \rangle \). Here, the notation of the intermediate spin quantum numbers, i.e. \( s_{12} \) and \( s_{123} \), is changed in comparison to App. A1. Intermediate spins are now numbered with respect to their order of appearance in the coupling scheme and additionally overlined. This notation has a clear advantage if larger spin systems are investigated and is used in the following. In order to clarify which spins are coupled, the single-spin quantum numbers \( s_i \) can also be found in the ket. It would not
be necessary to include them since they appear as fixed
numbers, but it turns out to be more convenient.

FIG. 15: Successive coupling of four spins \( s = 1 \). The (red)
subscripts denote the multiplicity, i.e. the number of paths
leading to the spin quantum number. The gray numbers refer
to the spin quantum numbers of the coupled single spins. On
the left the coupling scheme is indicated.

Now, if the coupling scheme is chosen and the frame-
work of the resulting basis states is fixed, one has to
construct the basis states by finding those values of the
intermediate spins that are valid according to Eq. \( \text{[A1]} \). 
This procedure can be visualized by constructing a cou-
pling pyramid as it is shown in Fig. 15. In Fig. 15
four spins with \( s = 1 \) are successively coupled in order
to yield the values of the total-spin quantum number \( S \).
The (red) subscripts next to the quantum numbers of the in-
termediate spins denote the number of different paths
leading to the spin quantum numbers of the coupled single spins, i.e. \( s_i = 1 \). For the sake of clarity, on the left of Fig. 15 the underlying coupling scheme is given once more.

FIG. 16: Pairwise coupling of four spins \( s = 1 \). The (red)
subscripts denote the multiplicity, i.e. the number of paths
leading to the spin quantum number. The gray numbers refer
to the spin quantum numbers of the coupled single or in-
termediate spins. On the left the coupling scheme is indicated.

Of course, a successive coupling scheme is not the only
possible way to couple the single spins \( s_j \) to a total spin \( S \).
For example, the construction of quasi-classical states as
described in Refs. [38] and [39] requires a different coupling
scheme. There, a coupling scheme is chosen in which
spins belonging to a certain sublattice are coupled in or-
der to get the total sublattice spin that is afterwards
coupled to the total spin of the system. In Fig. 16 a cou-
pling pyramid for a different coupling scheme of a spin
square is shown. The spins \( s_1, s_2, s_3, s_4 \) are coupled
to yield intermediate spins \( S_1 \) and \( S_2 \), respectively. The
intermediate spins are then coupled to the total spin \( S \).

The resulting multiplicity of states with the same
quantum number \( S \) is obviously independent of the cho-
zen coupling scheme. At this point it is important to real-
ize once again that these states, although resulting from
different coupling schemes, form basis sets of the same
Hilbert space \( H \). In the case of a square the coupling of
four single spins \( s = 1 \) discussed above results in basis
states that span the subspaces \( H(S) \) with \( S = 0, 1, \ldots, 4 \).
Writing this result in a different way using Eq. \( \text{[22]} \), one
obtains for the direct product of the irreducible represen-
tations \( D^{(1)} \) of the single spins the following expression:

\[
D^{(1)} \otimes D^{(1)} \otimes D^{(1)} \otimes D^{(1)} = 3 \cdot D^{(0)} + 6 \cdot D^{(1)} + 6 \cdot D^{(2)} + 3 \cdot D^{(3)} + 1 \cdot D^{(4)} .
\]

The knowledge of the dimensions of the resulting irre-
ducible representations, i.e. subspaces \( H(S) \), is a central
task whenever performing numerical exact diagonalization.
Deduced from a successive coupling of the spins, the
dimensions \( \dim H(S) \) can be calculated by a simple
recurrence formula.

The number of paths leading to a certain combination
\((S,n)\) is denoted by \( d_S \). \( n \) refers to the number of partic-
ipating spins in each step and runs from 1 to \( N \). \( n \) can
also be seen as labeling the rows of the coupling pyramid
for a successive coupling (see Fig. 15). In the case of a
different coupling scheme. At this point it is important to real-
ize once again that these states, although resulting from
different coupling schemes, form basis sets of the same
Hilbert space \( H \). In the case of a square the coupling of
four single spins \( s = 1 \) discussed above results in basis
states that span the subspaces \( H(S) \) with \( S = 0, 1, \ldots, 4 \).
Writing this result in a different way using Eq. \( \text{[22]} \), one
obtains for the direct product of the irreducible represen-
tations \( D^{(1)} \) of the single spins the following expression:

\[
D^{(1)} \otimes D^{(1)} \otimes D^{(1)} \otimes D^{(1)} = 3 \cdot D^{(0)} + 6 \cdot D^{(1)} + 6 \cdot D^{(2)} + 3 \cdot D^{(3)} + 1 \cdot D^{(4)} .
\]

The knowledge of the dimensions of the resulting irre-
ducible representations, i.e. subspaces \( H(S) \), is a central
task whenever performing numerical exact diagonalization.
Deduced from a successive coupling of the spins, the
dimensions \( \dim H(S) \) can be calculated by a simple
recurrence formula.

The number of paths leading to a certain combination
\((S,n)\) is denoted by \( d_S \). \( n \) refers to the number of partic-
ipating spins in each step and runs from 1 to \( N \). \( n \) can
also be seen as labeling the rows of the coupling pyramid
for a successive coupling (see Fig. 15). In the case of a
homonuclear system with \( N \) spins \( s \), the multiplicity
\( d_S(S,n+1) \) is given by

\[
d_S(S,n+1) = \sum_{S' = |S-s|}^{\min(S+s,n,s)} d_S(S',n) , \quad \text{(A17)}
\]

where \( S \) lies in the interval that is bounded by

\[
(n+1)s \geq S \geq \begin{cases} 0 & \text{if } 2s(n+1) \text{ even} \\ \frac{1}{2} & \text{if } 2s(n+1) \text{ odd} \end{cases} \quad \text{(A18)}
\]

according to a vector coupling rule (cf. Eq. \( \text{[A1]} \)). The
number of paths leading to a certain quantum number \( S \)
for one spin is just

\[
d_S(S,1) = \begin{cases} 1 & \text{if } S = s \\ 0 & \text{else} \end{cases} . \quad \text{(A19)}
\]

The dimension of the Hilbert space \( H(S) \) is then given
by \( \dim H(S) = d_S(S,N) \cdot (2S+1) \).
The dimensions within a heteronuclear spin system, i.e. a system with different values of single-spin quantum numbers, are obtained along the same route. However, the range of valid values for \( S \) has to be calculated for each step of recurrence separately, in contrast to the use of Eq. (A18). Furthermore, the sum in Eq. (A17) would run from \( S' = |S - s_i| \) to \( \min(S + s_i, \sum_{i=1}^{n} s_i) \) where the spin quantum number of every single spin \( s_i \) is individually labeled by the index \( i \).

3. The Heisenberg Hamiltonian expressed as irreducible tensor operator

In order to determine the spectra of magnetic molecules as it is done throughout this work, the Heisenberg Hamiltonian of Eq. (31) has to be expressed as irreducible tensor operator. In this section a general expression for the Heisenberg Hamiltonian is presented which can be used as a starting point for the calculation of the energy spectrum using the irreducible tensor operator approach.

**spin dimer** - The first step in finding an expression for the Heisenberg Hamiltonian in the form of an irreducible tensor operator is done by considering a spin dimer. The Hamiltonian of the dimer takes the simple form

\[
H_{\text{dimer}} = -J \mathbf{s}_1 \cdot \mathbf{s}_2 .
\]  

(A20)

Now, using Eq. (13) the above Eq. (A20) can easily be reproduced. Since the Heisenberg term is given by a scalar product, the corresponding compound irreducible tensor operator is of rank \( k = 0 \). Using Eqs. (12) – (15) one finds the expression

\[
\left\{ \tilde{s}^{(1)}(1) \otimes \tilde{s}^{(1)}(2) \right\}^{(0)} = \\
\sum_{q_1, q_2} C_{q_1 q_2}^{110} \tilde{s}_q^{(1)}(1) \tilde{s}_q^{(1)}(2) \\
= \frac{1}{\sqrt{3}} \left( \tilde{s}_0^{(1)}(1) \cdot \tilde{s}_0^{(1)}(2) + \tilde{s}_1^{(1)}(1) \cdot \tilde{s}_1^{(1)}(2) - \tilde{s}_0^{(1)}(1) \cdot \tilde{s}_1^{(1)}(2) \right) \\
= -\frac{1}{\sqrt{3}} \mathbf{s}_0(1) \cdot \mathbf{s}_0(2) .
\]

Thus, the tensorial form of the Heisenberg Hamiltonian of a spin dimer is

\[
H_{\text{dimer}} = \sqrt{3} J \left\{ \tilde{s}_0^{(1)}(1) \otimes \tilde{s}_0^{(1)}(2) \right\}^{(0)} .
\]  

(A21)

**spin triangle** - Since the tensorial form of \( H_{\text{dimer}} \) in Eq. (A21) describes a simple bilinear spin-spin interaction, an expression for a general Heisenberg Hamiltonian can now be developed. As a first extension a spin triangle is considered. The Hamiltonian that has to be converted to an irreducible tensor operator is

\[
H_\Delta = -J \left( \mathbf{s}_1 \cdot \mathbf{s}_2 + \mathbf{s}_2 \cdot \mathbf{s}_3 + \mathbf{s}_3 \cdot \mathbf{s}_1 \right) .
\]  

(A22)

In a very general form the successive coupling of three single-spin irreducible tensor operators of ranks \( k_1, k_2 \) and \( k_3 \) leads to

\[
T^{(k)}(k_1, k_2, k_3, \{k_i\}) = \\
\left\{ \tilde{s}^{(k)}(1) \otimes \tilde{s}^{(k)}(2) \right\}(\{k_i\}) \otimes \tilde{s}^{(k)}(3)(k) .
\]

(A23)

Here \( k \) denotes the rank of the resulting irreducible tensor operator and \( k_i \) the rank of the intermediate (coupled) one. The ranks of the many-particle tensor operators are given by the coupling rules for spin quantum numbers known from the spin vector coupling. For example, the rank \( k_1 \) is given by \( k_1 = |k_1 - k_2|, |k_1 - k_2| + 1, \ldots, k_1 + k_2 \) with \( k \) being determined accordingly. It must be emphasized that \( T^{(k)} \) includes all spin-spin interactions of a trimeric spin system, and thus it has to be specified in order to give the desired tensorial formulation of \( H_\Delta \).

With \( \mathbf{s}_0(0) = 1 \) and the tensorial expression found for a bilinear coupling in Eq. (A21), one arrives at

\[
H_\Delta = \sqrt{3} J \left( T^{(0)}(1, 1, 0, 0) + T^{(0)}(1, 0, 1, 1) + T^{(0)}(0, 1, 1, 1) \right) \\
= \sqrt{3} J \sum_{<i,j>} T^{(0)}_{ij}(\{k_i\}, \{k_j\}) .
\]

(A24)

The notation of \( T^{(0)}_{ij}(\{k_i\}, \{k_j\}) \) indicates that only the ranks of single-spin tensor operators \( i \) and \( j \) are chosen to equal 1 whereas the other tensor operators are of zero rank. The rank of the intermediate tensor operator \( k_i \) is fixed by the contributions of \( k_1 \) and \( k_2 \) to the zero-rank tensor operator \( T^{(k=0)} \).

Following Eqs. (A21) and (A24), the Heisenberg Hamiltonian of a general spin system is given by

\[
H_{\text{Heisenberg}} = \sqrt{3} \sum_{<i,j>} J_{ij} T^{(0)}(\{k_i\}, \{k_j\}) ,
\]

(A25)

where the irreducible tensor operator \( T^{(k)}(\{k_i\}, \{k_j\}) \) directly depends on the investigated system and the chosen coupling scheme for the coupling of the single-spin tensor operators \( \tilde{s}^{(k)}(i) \).

As an example, the resulting expression for the general, tetrameric tensor operator \( T^{(k)} \) in the case of a spin square shall be presented. The underlying coupling scheme of the single-spin tensor operators is chosen to
be pairwise because it is often advantageous to couple this way when additionally point-group symmetries are used (see App. A5). Then, the general irreducible tensor operator of a tetrameric system takes the form

\[
\mathbf{T}^{(k)}(k_1, k_2, k_3, k_4, \bar{k}_1, \bar{k}_2) = \left\{ \left. \left\{ \mathbf{S}(k_1)(1) \otimes \mathbf{S}(k_2)(2) \right\}^{(\bar{k}_1)} \right\} \otimes \left\{ \left. \left\{ \mathbf{S}(k_3)(3) \otimes \mathbf{S}(k_4)(4) \right\}^{(\bar{k}_2)} \right\} \right\}^{(k)}.
\]

The values of the ranks appearing in Eq. (A26) for the spin square modeled by a Heisenberg Hamiltonian are tabulated in Tab. I. The rows refer to the nearest-neighbor interaction \(<i,j>\) between single spins \(i\) and \(j\).

**TABLE I**: Values of the ranks for a spin square described by a Heisenberg Hamiltonian. The rows refer to the nearest-neighbor interaction \(<i,j>\) between single spins \(i\) and \(j\).

The general irreducible tensor operator of the tetrameric system \(\mathbf{T}^{(k)}\) based on a pairwise coupling scheme was already presented in Eq. (A26). The values of the ranks appearing in \(\mathbf{T}^{(k=0)}(\{k_i\}, \{\bar{k}_i\})\) are tabulated in Tab. I. The pairwise coupling scheme in the used construction of \(\mathbf{T}^{(k)}\) corresponds to basis states of the form

\[
|\alpha S M\rangle = |s_1 s_2 \bar{s}_1 s_3 s_4 \bar{s}_2 S M\rangle.
\]

By the application of the Wigner-Eckart theorem the calculation of the matrix elements of \(\mathbf{H}_\square\) is now – apart from the prefactor and the summation over the nearest-neighbor interactions according to Eq. (A27) – reduced to the evaluation of terms like

\[
\langle \alpha S M | T_{\square}^{(0)}(\{k_i\}, \{\bar{k}_i\}) | \alpha' S' M' \rangle = (-1)^{S-M} \begin{pmatrix} S & 0 & S' \\ -M & 0 & M' \end{pmatrix} \times \langle s_1 s_2 \bar{s}_1 s_3 s_4 \bar{s}_2 S | T_{\square}^{(0)} | s_1 s_2 \bar{s}_1 s_3 s_4 \bar{s}_2 S' \rangle.
\]

In the case of a square four such terms appear in \(\mathbf{H}_\square\) differing from each other by the values of \(\{k_i\}\) and \(\{\bar{k}_i\}\).

Since the Wigner-3J symbol in Eq. (A28) is reduced to

\[
\begin{pmatrix} S & 0 & S' \\ -M & 0 & M' \end{pmatrix} = \frac{(-1)^{S-M}}{\sqrt{2S+1}} \cdot \delta_{S,S'} \delta_{M,M'}.
\]

Eq. (A28) is reduced to

\[
\langle \alpha S M | T_{\square}^{(0)}(\{k_i\}, \{\bar{k}_i\}) | \alpha' S M \rangle = \frac{(-1)^{2(S-M)}}{\sqrt{2S+1}} \cdot \langle s_1 s_2 \bar{s}_1 s_3 s_4 \bar{s}_2 S | T_{\square}^{(0)} | s_1 s_2 \bar{s}_1 s_3 s_4 \bar{s}_2 S \rangle.
\]

Since all matrix elements between states of different \(S\) and \(M\) vanish, it becomes obvious that all calculations can be performed in subspaces \(H(S, M)\). Furthermore, because \(\mathbf{H}_\square\) is independent of an external magnetic field and thus no \(M\)-dependence of the energies is given, the spectrum can be evaluated in subspaces \(H(S,M = S)\).

Following Eq. (A29) the matrix elements can directly be obtained by determining the reduced matrix elements of \(T_{\square}^{(0)}\). By a successive application of Eq. (19), i.e. a successive decoupling of \(T_{\square}^{(0)}\), the reduced matrix elements are traced back to the reduced matrix elements of single-spin tensor operators that are given in Eqs. (17) and (18) for \(k = 0, 1\).

For the reduced matrix element of \(T_{\square}^{(k)}\) the decoupling yields
\[
\langle s_1 s_2 \bar{S}_1 s_3 s_4 \bar{S}_2 S \mid T^{(k)} \mid s_1 s_2 \bar{S}_1 s_3 s_4 \bar{S}_2 S' \rangle = \\
\left[ (2S + 1)(2S' + 1)(2k + 1) \right]^{\frac{3}{2}} \left[ (2S + 1)(2S'_2 + 1)(2k_2 + 1) \right]^{\frac{3}{2}} \left[ (2S_1 + 1)(2S'_1 + 1)(2k_1 + 1) \right]^{\frac{3}{2}}.
\]

In the case of \( H_\Box \), the appearing ranks of the tensor operators can be found in Tab. I and \( S' \) is forced to be \( S' = S \) by the Wigner-3J symbol in Eq. (A28).

The clear structure of the resulting expression for a reduced matrix element in Eq. (A30) now allows one to write a highly flexible and structured computer program that takes over the calculation and diagonalization of the Hamilton matrix. Regarding the calculation of the matrix elements, a recurrence formula can be implemented which decouples the irreducible tensor operator of the system step-by-step.\(^{119}\)

5. Using point-group symmetries

General considerations concerning the use of point-group symmetries in Heisenberg spin systems have already been presented in Secs. IID and IIE. Now, as a clarification of these considerations, a \( \pi \)-rotation around the central \( C_2 \)-axis of a spin square is considered (cf. Fig. 17). According to a successive coupling scheme, the vector-coupling basis states are given in the form \(| s_1 s_2 \bar{S}_1 s_3 \bar{S}_2 s_4 S M \rangle \). It must be emphasized here that the underlying coupling scheme, that determines the way how basis states are constructed, can be chosen independently from any symmetry considerations, although a suitable choice will reduce the calculations as is discussed below.

![Figure 17: Sketch of a spin square with \( D_4 \)-symmetry operations.](image)

Figure 17 shows the coupling graph of the square with \( D_4 \)-symmetry operations. The operations are labeled with respect to \( n \)-fold rotations around the given axes.

\[
| s_1 s_2 \bar{S}_1 s_3 \bar{S}_2 s_4 S M \rangle = \\
\sum_{m_1 = M} \frac{C^{s_1 s_2 \bar{S}_1}}{M_1} \cdot \frac{C^{s_3 \bar{S}_2}}{M_3} \cdot \frac{C^{s_4 S}}{M_4} \cdot | m_1 m_2 m_3 m_4 \rangle.
\]

The summation indices are entirely determined by the constraint \( \sum_{i} m_i = M \). The values of the intermediate magnetic quantum numbers \( M_i \) can be deduced from the magnetic quantum numbers of the involved single spins, i.e. \( M_1 = m_1 + m_2 \) and \( M_2 = M_1 + m_3 \).

Following Eqs. (26) and (A31), performing the \( \pi \)-rotation described by the operator \( \hat{G}(3412) \) results in the expression

\[
\hat{G}(3412) | s_1 s_2 \bar{S}_1 s_3 \bar{S}_2 s_4 S M \rangle = \\
\sum_{m_1 = M} \frac{C^{s_1 s_2 \bar{S}_1}}{M_1} \cdot \frac{C^{s_3 \bar{S}_2}}{M_3} \cdot \frac{C^{s_4 S}}{M_4} \cdot | m_3 m_4 m_1 m_2 \rangle.
\]

Due to the performed permutation on the product states the resulting state cannot easily be represented as a
vector-coupling state belonging to the former coupling scheme given by the successive addition of spin operators: \( s_1(1) + s_2(2) = \mathbf{S}(1) \), \( \mathbf{S}(1) + s(3) = \mathbf{S}(2) \), and \( \mathbf{S}(2) + s(4) = \mathbf{S} \).

At this point, it becomes obvious that the operator \( G \) is inducing a transition from the coupling scheme, according to which the basis states have initially been constructed, to another one. A proper re-labeling of the summation indices in the sum of Eq. \((A32)\) with respect to a point-group operation \( R^{-1} \), i.e., a \( (-\pi) \)-rotation around the central \( C_2 \)-axis, reveals the resulting coupling scheme in which \( G(3412) \{s_1s_2s_1s_3s_4s_SM\} \) can be represented as a vector-coupling state \( \mathbf{S} \). In this special case one finds that \( G(3412) \) is inducing a transition to a coupling scheme given by \( s(3) + s(4) = \mathbf{S}(1') \), \( \mathbf{S}(1') + s(1) = \mathbf{S}(2') \), and \( \mathbf{S}(2') + s(2) = \mathbf{S} \). As a shorthand notation one can write

\[
\left| s_1s_2s_1s_3s_2s_4s_SM \right> \xrightarrow{G(3412)} \left| s_3s_4s_1s_1s_2s_2s_SM \right>,
\]

with the limitation that this expression does not give the concrete values of the appearing quantum numbers of the states. Nevertheless, it illustrates the transition between vector-coupling states of different and thus independent coupling schemes.

Following Eq. \((28)\) the action of the \( \pi \)-rotation on a vector-coupling state of the chosen form results in

\[
G(3412) \left| s_1s_2s_1s_3s_2s_4s_SM \right> = \sum_{s_1',s_2'} \delta_{s_1,s_1'} \delta_{s_2,s_2'} \left| s_1s_2s_1's_3s_2's_4s_SM \right> \times \left< s_1s_2s_1's_3s_2's_4s_SM \left| s_3s_4s_1s_1's_2's_2s_SM \right> \right.\]

As mentioned in Sec. II D the main task when calculating the action of a point-group operation on a vector-coupling state is the determination of the general recoupling coefficients connecting states of the initial and the resulting coupling scheme. Generating a formula for general recoupling coefficients can only be performed in a rather advanced procedure (see Sec. B).

FIG. 18: Visualization of two possible couplings for the square: successive coupling scheme (l.h.s.) and pairwise coupling scheme (r.h.s.).

Regarding the recoupling coefficients that appear when performing point-group operations, a very helpful simplification shall be mentioned here. From Eq. \((A32)\) it can be seen that the action of the operator \( G(3412) \) on the product states prevents the re-expression of the resulting linear combination of product states as a simple vector-coupling state belonging to the initial coupling scheme. However, the choice of the coupling scheme according to which the initial basis was constructed is somewhat arbitrary. In order to minimize the computational effort, which is directly related to the number of states with non-zero recoupling coefficient in Eq. \((A33)\), one has to choose a non-successive coupling scheme. A favorable coupling scheme of this kind is shown in Fig. 18. This scheme is referred to as pairwise coupling scheme and the basis states look like \( |s_1s_2s_3s_4s_2s_SM\rangle \). The \( \pi \)-rotation around the central \( C_2 \)-axis of the square now induces a transition that can be symbolized by

\[
|s_1s_2s_3s_4s_2s_SM\rangle \xrightarrow{G(3412)} |s_3s_4s_1s_1s_2s_2s_SM\rangle
\]

and leads according to Eq. \((27)\) to a recoupling coefficient of the form

\[
\langle s_1s_2s_3s_4s_2s_SM|s_3s_4s_1s_1s_2s_2s_SM \rangle.
\]

Now, the calculation of a formula for this recoupling coefficient is trivial since the intermediate spin operators of the initial and the resulting coupling scheme are mutually the same, i.e., \( s(1) = \mathbf{S}(2) \) and \( s(2') = \mathbf{S}(1) \). Unfolding \( |s_3s_4(\mathbf{S}_1' = \mathbf{S}_2)s_1s_2(\mathbf{S}_2' = \mathbf{S}_1)SM\rangle \) into a linear combination of product states in analogy to Eq. \((A31)\) leads to

\[
|s_3s_4s_1s_2s_1s_SM\rangle = \sum_{m_1,M} \sum_{m_2,M} C^{s_3s_4s_2}_{m_1 m_2 M} C^{s_1s_2s_1}_{m_1 m_2 M} C^{s_2s_1}_{m_2 M} |m_1 m_2 m_4 \rangle.
\]

In order to convert the Clebsch-Gordan coefficients to a form that appears when unfolding states of the form \( |s_1s_2s_3s_4s_2s_SM\rangle \) one simply has to use the symmetry property of the Clebsch-Gordan coefficients from Eq. \((A5)\). This leads to

\[
C^{s_2s_2s}_{M_2 M_1 M} = (-1)^{1}s_1s_2s_C^{s_2s_2s}_{M_2 M_1 M} ,
\]

and thus an expression for the recoupling coefficient is obtained which only contains one simple phase factor:

\[
\langle s_1s_2s_3s_4s_2s_SM|s_3s_4s_1s_1s_2s_2s_SM \rangle = (-1)^{s_1+s_2-s}.
\]

The action of the operator performing a \( \pi \)-rotation on a state belonging to the pairwise coupling scheme mentioned above therefore directly results in a state belonging to the same coupling scheme with an attached phase factor. Thus, it has been shown that with a cleverly chosen coupling scheme the computational effort, that is required for the calculation of symmetrized basis states according to Eq. \((25)\), can be minimized. The graphical visualization of possible coupling schemes in a square
shown in Fig. 18 makes it obvious that one will find a simple recoupling formula depending only on phase factors whenever one can find a coupling scheme that is invariant under the performed symmetry operation. Since one has to sum over all symmetry operations of the group in order to construct symmetricized basis states of a given irreducible representation (see Eq. (23)), the underlying coupling scheme should be chosen in such a way as to simplify all or at least most of the resulting recoupling coefficients. This means that the coupling scheme should be invariant under all or at least most of the symmetry operations.

However, one will not always be able to find a coupling scheme that simplifies the calculation of the recoupling coefficients as shown above. Especially if the system under consideration is exhibiting three-fold symmetry axes, such a procedure turns out to be impossible by means of a pairwise coupling scheme. In this case a generalization of finding a recoupling formula independent of the choice of the coupling scheme becomes necessary.

### 6. Computational effects of the choice of the coupling scheme

The computational realization of the theoretical background presented in this work has been a central task. The performed calculations would not have been possible without developing a highly parallelized computer program that is well adapted to the use in a high performance computing environment. In this section some remarks on the computational effects of the choice of the underlying coupling scheme shall be given. In general, as long as a proper scaling is achieved the most intuitive way to speed up calculations using high performance computers is to distribute calculations among many processing units. Nevertheless, as will be seen below the right choice of initial parameters like the coupling scheme can help to ease the problem of calculating energy spectra and thermodynamic properties of magnetic molecules.

Since several terms appear in this section which might be unknown to the reader, their particular meaning as well as related aspects shall be discussed first. The term computation time refers to the cumulative time that is needed in order to perform a certain number of floating point operations (FLOPs). The execution time refers to the runtime of the considered part of the program. Assuming a parallel execution of the program with optimal performance, the computation time remains unchanged although the operations are performed in parallel. A reduction of the computation time can be achieved by reducing the number of FLOPs that have to be performed. In contrast to this, the execution time usually decreases with increasing number of processing units. The change of the execution time as a function of the used processing units is called scaling behavior. It is referred to as optimal if the execution time is divided by two whenever the number of used processing units is doubled. The speed up $S$ using $p$ processing units is defined as

$$S = \frac{T_1}{T_p},$$

where $T_1$ and $T_p$ refer to the execution times of the sequential and the parallelized algorithm, respectively. An optimal speed up corresponds to $S = p$. The optimal speed up can be achieved if the whole source code can be parallelized without dependencies between the operations which are executed in parallel. Practically, sequential regions and communication between the processing units often limit the speed up to a value that is lower than the number of used processing units.

In general, the computational realization of the presented framework can be divided into two completely independent parts. On the one hand a matrix representation of the Hamiltonian is set up with the help of the irreducible tensor operator approach. On the other hand this matrix or independent blocks of it are diagonalized, i.e. the eigenvalues and eigenvectors are determined numerically. If point-group symmetries are used, a very decisive role concerning the computation time is played by the construction of symmetrized basis states. These functions appear as linear combinations of the initial basis states. The weight of the states that are included in these linear combinations is determined by general recoupling coefficients. If a coupling scheme can be found that is invariant under all point-group operations, the number of states that contribute to a linear combination representing a symmetrized basis state is minimized. As already mentioned, a reduction of computation time is achieved by choosing a coupling scheme that minimizes the number of appearing summation indices and Wigner-6J symbols.

The construction of symmetrized basis states plays an important role for extending the limits of numerical exact diagonalization with the help of the concepts presented in this work. Whenever the dimensions of the appearing matrices are to be reduced by the incorporation of point-group symmetries, a certain amount of additional computation time has to be spent on the construction of symmetrized basis states. Since the construction procedure cannot easily be parallelized, the use of more processing units within this particular region does not always lead to the desired reduction of execution time. In any case, one has to ensure that the recoupling formulas, which determine the number of performed FLOPs, are the simplest in order to reduce computation time. As already mentioned, this can be achieved by choosing a coupling scheme that is invariant under the operations of the assumed point-group. The resulting recoupling formulas do then not contain Wigner symbols and are optimal.

In Fig. 19 the execution times for the determination of the energy eigenvalues of a cuboctahedron with $s = 3/2$ in the subspace $H(S = 0, M = 0, A_1)$ are shown in dependence on the chosen coupling scheme. The used point-group symmetry has been $D_4$ and execution times are given for the the choice of a completely invariant and a
non-invariant coupling scheme, respectively. Comparing the scaling behavior, one can see that the performance of both calculations is limited by the construction of the symmetrized basis states. Furthermore, it becomes obvious that the set up of the matrices is heavily influenced by the particular form of the symmetrized basis states. In the case of the non-invariant coupling scheme the set up of the matrix has been much slower than in the case of the invariant coupling scheme because the symmetrized basis states involve more states of the initial (vector-coupling) basis.

Appendix B: The calculation of general recoupling coefficients

In this section graph-theoretical considerations are presented that allow to determine the action of point-group operations on vector-coupling states. It is shown how a general recoupling formula can be developed from mapping general Wigner coefficients on binary trees or Yutsis graphs.

In general, the problem of calculating recoupling coefficients has to be divided into two parts. The first part is the generation of a formula that describes the transition between two different coupling schemes. The second – and much easier – part is the evaluation of a given formula using a specific set of quantum numbers. This section is exclusively focused on the first part, i.e. the generation of a recoupling formula that links different coupling schemes in systems with an arbitrary number of participating spins which turns out to be more difficult.

1. Binary trees

In the literature one can find successful implementations that deal with the generation of formulas for general recoupling coefficients which only involve a series of phase factors and Wigner-6J symbols. The most intuitive way of generating a recoupling formula is to operate on so-called binary trees. The correspondence between a binary tree and a given coupling scheme is rather obvious. Each coupling of two spins $s_a$ and $s_b$ to a compound spin $s_c$ forms a triad that corresponds to an elementary binary tree shown in Fig. 20. This tree is composed of only three angular momenta and can simultaneously be seen as representing a Clebsch-Gordan coefficient. From such elementary trees a binary tree can be built up step-by-step that represents the chosen coupling scheme. The tree constructed this way then contains all Clebsch-Gordan coefficients that result from the decomposition of a vector-coupling state belonging to the particular coupling scheme into product states (cf. Eqs. (A13) and (A14)).

Operating on binary trees in order to generate a formula for a general recoupling coefficient directly leads to the procedure that limits the resulting expressions to 6J symbols. Here, the generation of a formula for the recoupling coefficient $\langle s_1s_2\frac{S_3}{2}\frac{S_4}{2}s_4SM|s_3s_4\frac{S_1}{2}\frac{S_2}{2}s_2SM \rangle$, that appears in Eq. (A33), shall be presented. In this case, generating a recoupling formula corresponds to finding a transition between the binary trees that are shown in Fig. 21. In other words, one transforms the set of Clebsch-Gordan coefficients that is represented by the initial tree (l.h.s. of Fig. 21) to the set that is represented by the targeted tree (r.h.s. of Fig. 21).

Following the usual graph-theoretical name convention the single-spin quantum numbers are referred to as leave nodes while the intermediate spin quantum numbers are called coupled nodes. The total-spin quantum number appears as a coupled node of a special kind and is called root.

There are in general two types of operations that have to be performed in a certain manner in order to yield the desired form of the recoupling coefficient. These operations are shown in Fig. 22, and are called an exchange operation and a flip operation. Both operations are only performed on subtrees of the initial tree, thus only leading to changes in the particular subtree while leaving the rest of the tree unchanged. With every operation a certain contribution to the recoupling formula is obtained.

An exchange operation refers to a recoupling coefficient
that appears when considering the recoupling of two spins \( s_a \) and \( s_b \) within a single triad. Obviously, the only way of recoupling these spins is to perform an exchange between them. The effect of this operation can easily be derived from unfolding the vector-coupling states \(|s_a s_b s_c\rangle\) and \(|s_b s_a s_c\rangle\) in terms of product states according to Eq. (A4). A state of the form \(|s_a s_b s_c\rangle\) can be written as a state of the form \(|s_b s_a s_c\rangle\) by using the symmetry property of the Clebsch-Gordan coefficients from Eq. (A5), leading to a recoupling coefficient

\[
\langle s_a s_b s_c | s_b s_a s_c \rangle = (-1)^{s_a + s_b - s_c}.
\]

(B1)

In analogy, a flop operation refers to the recoupling of three spins \( s_a \), \( s_b \), and \( s_c \). Denoting the intermediate spin by \( s_d \) and the total spin by \( s_f \), a successive coupling scheme would lead to states that can be written as \(|s_a s_b s_d s_f\rangle\). However, a second coupling scheme can be designed that results in states of the form \(|s_a s_b s_c s_f\rangle\). By definition a transition between these coupling schemes is described by a Wigner-6J symbol resulting in

\[
\langle s_a s_b s_d s_f | s_a s_b s_c s_f \rangle = (-1)^{s_a + s_b + s_c + s_f} \sqrt{(2s_d + 1)(2s_c + 1)}
\]

\[
\times \begin{cases} s_a & s_b & s_d \\ s_c & s_f & s_c \end{cases}.
\]

(B2)

It has to be mentioned that the flop operation shown in Fig. 22(b) was assumed to create a node, i.e. a spin quantum number that already exists in the targeted coupling scheme, namely \( s_c \). Whenever a flop operation is performed that creates a node which is unknown in the targeted coupling scheme, a summation variable has to be introduced within the resulting contribution to the recoupling formula. This summation variable is completely determined by the symmetry of the appearing Wigner-6J coefficient. The contribution resulting from a flop operation that creates an unknown node \( s_c' \) within the binary tree would look like

\[
(-1)^{s_a + s_b + s_c + s_f} \sum_{s_c'} \sqrt{(2s_d + 1)(2s_c + 1)}
\]

\[
\times \begin{cases} s_a & s_b & s_d \\ s_c & s_f & s_c' \end{cases}.
\]

The desired formula for the recoupling coefficient from Eq. (A33) is now obtained by performing a proper sequence of exchange and flop operations. This sequence is in detail displayed in Fig. 23. It is not the only possible sequence of operations on the binary tree that leads to a recoupling formula for the discussed transition. However, in this simple case the displayed sequence leads to an optimal formula minimizing the number of resulting Wigner-6J symbols.
The result of the operations then reads
\[
(s_1s_2S_1S_2s_3s_4s_5SM|s_3s_4S_1S_1's_2's_2SM) = \sqrt{(2S_1 + 1)(2S_2 + 1)(2S_3 + 1)(2S_4 + 1)(2S_5 + 1)} \\
\times (-1)^{s_1 + s_2 + s_3 + s_4 + s_5 + 1} \left( \begin{array}{ccc}
S_1 & s_3 & S_2 \\
S_4 & S & S_1'
\end{array} \right) \left( \begin{array}{ccc}
s_2 & s_1 & S_1' \\
S & S_2 & S_2'
\end{array} \right).
\]

(B3)

This simple form was only reached because the flop operations shown in Figs. 23(a) and 23(c) create nodes that already exist in the final coupling scheme, i.e. $S_1'$ and $S_2'$.

As long as such simple recoupling coefficients are considered, the process of determining a proper sequence leading from the initial coupling scheme to the targeted one can be easily done by hand and does not need any automatization. Nevertheless, more sophisticated problems result in transitions between binary trees that cannot be treated. Then, it becomes necessary to set up an algorithm that automatically creates a proper -- ideally optimal -- sequence. Regarding binary trees, known implementations\textsuperscript{110,111} of such algorithms can be seen as trial-and-error procedures.

By performing a subsequence of operations, initially containing only one exchange or flop operation, one tries to find a tree containing a node that is known in the targeted coupling scheme. Whenever it is impossible to find such a tree with the given number of operations in the subsequence, the number of considered operations is increased, i.e. the subsequence is extended. A successful implementation of this procedure leads to a stepwise creation of the targeted tree in which each step is guaranteed to be performed with the smallest (overall) number of exchange and flop operations. However, the minimization of the number of operations within the performed sub-sequences does not assure that the resulting recoupling formula is optimal. In general, a recoupling formula is optimal if the number of occurring summation variables and Wigner-6J coefficients is minimal. Since summation variables and 6J symbols are only introduced by flop operations, generating an improved recoupling formula directly corresponds to reducing the number of performed flops.

2. Graph theoretical solution - Yutsis graphs

As it was shown in the last section, operating on binary trees in order to generate a recoupling formula involving only phase factors, square roots, and Wigner-6J symbols already leads to a simple and successful procedure. However, the process of determining an optimized sequence of operations remains concealed. In order to improve this process and thus improving the recoupling formula, ideas resulting from more advanced graph-theoretical considerations can be applied. In Refs.\textsuperscript{110,111,112,114} the problem of generating a recoupling formula was solved with the help of Yutsis graphs. This procedure, providing a technically more difficult, but at the same time theoretically more transparent way of generating an improved recoupling formula, shall be reviewed in this section.

The creation of Yutsis graphs is a straightforward task starting from the background given in App.\textsuperscript{B7}. In order to understand how these graphs evolve, an explanation of how to construct a Yutsis graph shall be given here. Additionally, the reduction of such a graph leading to an improved recoupling formula will be discussed briefly. The interested reader will find a deeper and more theoretical investigation of general features of Yutsis graphs in the literature\textsuperscript{110,111,112,114}.

As already discussed in Sec.\textsuperscript{A1} an expression for a recoupling coefficient in terms of Clebsch-Gordan coefficients or Wigner-3J symbols can be found by decomposing the bra and the ket states into sums of product states. From Eqs.\textsuperscript{B4} and\textsuperscript{B5} one immediately finds the ket state
\[
|s_1s_2S_1s_3S_2s_4SM = \sum_{\{m_1\}} \sum_{\{M_1\}} C(\alpha) \left( \begin{array}{ccc} s_1 & s_2 & S_1 \\
m_1 & m_2 & M_1 \end{array} \right) \left( \begin{array}{ccc} S_1 & s_3 & S_2 \\
M_1 & m_3 & M_2 \end{array} \right) \times \left( \begin{array}{ccc} S_2 & s_4 & S \\
M_2 & m_4 & M \end{array} \right) |m_1m_2m_3m_4\rangle,
\]

where $C(\alpha)$ contains the square roots as well as the phase factors that appear when transforming Clebsch-Gordan coefficients into Wigner symbols. The multiple sums run over all single-spin magnetic quantum numbers $m_i$ and the magnetic quantum numbers $M_i$ of the intermediate spins. The curly brackets are reminiscent of a generalized Wigner coefficient. The same decomposition yields for the bra state
\[
|s_3s_4S_1S_2s_2SM = \sum_{\{m_i\}} \sum_{\{M_i\}} C(\beta) \left( \begin{array}{ccc} s_3 & s_4 & S_1' \\
m_3 & m_4 & M_1' \end{array} \right) \left( \begin{array}{ccc} S_1' & s_1 & S_2' \\
M_1' & m_1 & M_2' \end{array} \right) \times \left( \begin{array}{ccc} S_2' & s_2 & S \\
M_2' & m_2 & M \end{array} \right) |m_1m_2m_3m_4\rangle.
\]

From Eqs.\textsuperscript{B4} and\textsuperscript{B5} one immediately finds the
following expression for the recoupling coefficient:
\[
\langle s_1 s_2 \Sigma_1 s_3 \Sigma_2 S M | s_3 s_4 \Sigma_1 s_1 \Sigma_2 s_2 SM \rangle = \sum_{\{m_i\}, \{m_i'\}} P^\alpha(\{m_i\}) \cdot P^\beta(\{m_i'\}) 
\times \langle m_1 m_2 m_3 m_4 | m'_1 m'_2 m'_3 m'_4 \rangle
\]  
(B6)
\[
= \sum_{\{m_i\}, \{m_i'\}} \delta_{\{m_i\}, \{m_i'\}} P^\alpha(\{m_i\}) \cdot P^\beta(\{m_i'\}) .
\]

The abbreviations $P^\alpha$ and $P^\beta$ stand for the generalized Wigner coefficients that depend on the quantum numbers of the underlying coupling schemes which the sets $\alpha$ and $\beta$ refer to. The derived expression for the recoupling coefficient in Eq. (B6) is still involving magnetic quantum numbers. Since a recoupling coefficient is in general independent of any magnetic quantum number, a simplification can be found that only involves spin quantum numbers. Such a simplification was already found in the former section with the help of binary trees and will now be discussed on the basis of Yutis's graphs.

The main idea of generating a recoupling formula with the help of Yutis's graphs is – in a first step – to set up a graphical representation of generalized Wigner coefficients as found in Eqs. (B4) and (B5). Afterwards, these graphs are joined in order to build up a Yutis graph that represents the recoupling coefficient. A simplification of the constructed Yutis graph according to special operations then leads to the desired formula that is independent of magnetic quantum numbers.

The building blocks of Yutis's graphs are diagrammatic representations of Wigner-3J symbols. Figure 24 shows two diagrammatic representations of the same Wigner-3J symbol

\[
\begin{pmatrix}
  s_a & s_b & s_c \\
  m_a & m_b & m_c
\end{pmatrix}.
\]

Such a representation consists of three lines and one node. With every spin quantum number in the Wigner symbol a line is identified. The three lines are connected by the node. The node is labeled with a (+) or (−) sign while the lines are characterized by the direction they are pointing in. The (−) sign denotes a clockwise orientation of the spin quantum numbers within the corresponding Wigner-3J symbol (cf. Fig. 24 r.h.s.) whereas the (+) sign indicates an anticlockwise ordering (cf. Fig. 24 l.h.s.). The free ends of the lines represent the projections of the spin quantum numbers, i.e. the magnetic quantum numbers $m_a$, $m_b$, and $m_c$. If a line leads away from the node, the corresponding magnetic quantum number appears with a positive sign in the Wigner symbol, whereas it appears with a negative sign if the line is directed towards the node.

It is obvious that any operation that changes the diagrams of the Wigner symbol in Fig. 25 will lead to a Wigner symbol that differs from the original one. Changing the sign of the node or simultaneously changing the directions of all lines results in a factor that can be obtained from the symmetry properties of the Wigner-3J symbols described in Sec. A1. The change of the sign corresponds to an uneven permutation of spins within the Wigner-3J symbol (cf. Eq. (A7)) while the change of all directions of the lines corresponds to multiplying the lower row of the original Wigner-3J symbol by $-1$ (cf. Eq. (A8)). Both operations result in a phase factor of $(-1)^{S_a+S_b+S_c}$ whereas any rotation of the diagram has no effect on the Wigner-3J symbol since the ordering remains unchanged.

In order to construct a graph that represents a generalized Wigner coefficient, another operation has to be introduced. As shown in Fig. 25, the diagrams of two Wigner symbols can be contracted if two lines exist that are labeled by the same quantum number and point into the same direction. The resulting graph then represents a summation over the corresponding magnetic quantum number given by

\[
\sum_{m_a} \begin{pmatrix}
  s_a & s_b & s_c \\
  m_a & m_b & m_c
\end{pmatrix} \begin{pmatrix}
  s_a & s_d & s_c \\
  -m_a & m_d & m_c
\end{pmatrix} .
\]  
(B7)

Figures 26(a) and 26(b) show graphical representations of the generalized Wigner coefficients as found in Eqs. (B4) and (B5). They are easily constructed following the conventions introduced above.

The arrangement of the diagrams representing generalized Wigner coefficients is chosen in such a way as to ease the contraction of both graphs and was proposed in Ref. 108. The graph representing the left hand side of the recoupling coefficient contains only negative nodes with the spins being ordered clockwise around these nodes. In the graph belonging to the right hand side of the recoupling coefficient the spins are ordered anticlockwise around the
FIG. 26: Graphical representation of the generalized Wigner coefficients for the coupling schemes contained in the recoupling coefficient \( \langle s_1s_2S_1S_2s_3s_4S_1' s_1' s_2' s_3 s_4 S'M \rangle \) as well as the resulting Yutsis graph.

FIG. 27: Operations on a Yutsis graph and resulting contributions to the recoupling formula.
as the signs of the nodes have to be considered carefully. Within the Yutsis graph that is supposed to be reduced these directions and signs eventually have to be changed in order to match the constellation of the edges and the nodes shown in Fig. 27. In this process the change of the direction of an edge $s$, i.e. a contracted line, contributes with $(-1)^{2s}$ to the phase of the recoupling coefficient.

The contributions to the recoupling formula arising from reducing the Yutsis graph according to the above mentioned operations are discussed in detail in Ref. 108 and shall not be further explained here for the sake of brevity.

A Yutsis graph is said to be reduced whenever a graphical representation is obtained that corresponds to the one in Fig. 25. This representation is called a triangular delta and gives a factor 1, if $s_a$, $s_b$, and $s_c$ satisfy the triangular condition (Eq. (A1)), and a factor 0 otherwise.

Coming back to the example of calculating the recoupling coefficient $(s_1s_2s_3s_4s_5s_7s_8s_9s_{10})$ that is displayed in Fig. 26(c) one immediately finds two 3-cycles which can be reduced in order to generate a recoupling formula: $s_1$-$s_2$-$s_9$ and $s_3$-$s_4$-$s_7$. As a result of this reduction, the recoupling formula contains apart from phase factors and square roots two Wigner-6J symbols as in Eq. (B3).

Using this information Fig. 27 shows the operations leading to a reduction of cycles that appear in the graph. A cycle refers to a loop that connects a certain number of nodes. Depending on the number of connected nodes, different operations exist that reduce the graph. Figure 27 shows the operations leading to a reduction of 2-, 3-, and 4-cycles. Additionally, an interchange operation is shown that can be used in order to express cycles which cannot be reduced immediately, i.e. cycles with more than four nodes, in terms of 2-, 3-, and 4-cycles.

The contributions $F$ to the recoupling formula resulting from the shown operations are listed in Tab. III. The values for the quantum numbers $k$ related to the relabeled edges in Figs. 27(c) and 27(d) are determined by the symmetry properties of the Wigner-6J symbols within these contributions. Whenever performing reductions on a Yutsis graph, the directions of the edges as well as the signs of the nodes have to be considered carefully. Within the Yutsis graph that is supposed to be reduced these directions and signs eventually have to be changed in order to match the constellation of the edges and the nodes shown in Fig. 27. In this process the change of the direction of an edge $s$, i.e. a contracted line, contributes with $(-1)^{2s}$ to the phase of the recoupling coefficient.

The contributions to the recoupling formula arising from reducing the Yutsis graph according to the above mentioned operations are discussed in detail in Ref. 108 and shall not be further explained here for the sake of brevity.

![Graphical representation of a triangular delta.](image)

**FIG. 28:** Graphical representation of a triangular delta.

**FIG. 29:** Reduction of the outer triangle of the Yutsis graph from Fig. 26(c).

However, as already mentioned in App. B 1 there is in general more than one possibility of reducing a graph. Figure 29 shows a possible first step that reduces the outer triangle of the Yutsis graph. The contributions $F$ to the recoupling formula resulting from the shown operations are listed in Tab. III. The values for the quantum numbers $k$ related to the relabeled edges in Figs. 27(c) and 27(d) are determined by the symmetry properties of the Wigner-6J symbols within these contributions. Whenever performing reductions on a Yutsis graph, the directions of the edges as well as the signs of the nodes have to be considered carefully. Within the Yutsis graph that is supposed to be reduced these directions and signs eventually have to be changed in order to match the constellation of the edges and the nodes shown in Fig. 27. In this process the change of the direction of an edge $s$, i.e. a contracted line, contributes with $(-1)^{2s}$ to the phase of the recoupling coefficient.

The contributions to the recoupling formula arising from reducing the Yutsis graph according to the above mentioned operations are discussed in detail in Ref. 108 and shall not be further explained here for the sake of brevity.

A Yutsis graph is said to be reduced whenever a graphical representation is obtained that corresponds to the one in Fig. 25. This representation is called a triangular delta and gives a factor 1, if $s_a$, $s_b$, and $s_c$ satisfy the triangular condition (Eq. (A1)), and a factor 0 otherwise.

Coming back to the example of calculating the recoupling coefficient $(s_1s_2s_3s_4s_5s_7s_8s_9s_{10})$ that is displayed in Fig. 26(c) one immediately finds two 3-cycles which can be reduced in order to generate a recoupling formula: $s_1$-$s_2$-$s_9$ and $s_3$-$s_4$-$s_7$. As a result of this reduction, the recoupling formula contains apart from phase factors and square roots two Wigner-6J symbols as in Eq. (B3).
The recoupling coefficient is given by each other. One possible expression for the recoupling slightly different but, can of course be transformed into a completed recoupling formula. These formulas look would then lead to a triangular delta and therefore to different triangles appear. The reduction of each triangle tribute to the phase of the recoupling coefficient. As directions of the edges are omitted since they only con-duction that contributes two Wigner-6J symbols to the of Fig. 26(c) only triangles appear leading to an easy re-duction in order to simplify the calculation of the Hamilton matrices saving hardware resources, but it also provides deeper insight into the physics of the system arising from its geometry.

So far, this section has dealt with the construction of a Yutsis graph and those operations that reduce this graph to a triangular delta. In principle, one could generate recoupling formulas and calculate general recoupling coefficients with this information. In the discussed example of Fig. 26(c) only triangles appear leading to an easy re-duction that contributes two Wigner-6J symbols to the recoupling formula. However, in larger systems with high symmetry often more complicated recoupling coefficients have to be calculated. In order to minimize the computational effort it is desirable to generate a formula that contains as few Wigner-6J symbols and summation indices as possible. Again, they result from triangles, squares, and cycles of higher order.

The most intuitive way of generating an improved recoupling formula is to reduce the smallest cycles first. This idea was implemented in Refs. [1112113] and already yields considerably improved formulas in comparison to the use of a trial-and-error technique. However, these formulas can be further improved by using a more sophisticated strategy of reducing cycles [118]

Summarizing this section, one can say that with the help of graph-theoretical methods the effect of general point-group operations on vector-coupling states can be determined. Once this effect is known, the eigenstates of the system under consideration can be labeled with respect to irreducible representations of the point group. This characterization not only reduces the dimensions of the Hamilton matrices saving hardware resources, but it also provides deeper insight into the physics of the system arising from its geometry.

\[ \langle s_1 s_2 s_3 s_4 s_5 s_6 | s_1 s_2 s_3 s_4 s_5 s_6 | S \rangle = \begin{vmatrix} s_1 & s_2 \\ s_3 & s_4 \end{vmatrix} \begin{vmatrix} s_1 & s_1 & s_2 & s_2 \\ s_3 & s_3 & s_4 & s_4 \end{vmatrix} \]
